Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide general guidance for commonly encountered clinical scenarios. The recommendations do not dictate the care for an individual patient. The ACR considers adherence to the recommendations described in this guideline to be voluntary, with the ultimate determination regarding their application to be made by the clinicians in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed and endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. ACR recommendations are not intended to dictate payment or insurance decisions, or drug formularies or other third-party analyses. Third parties that cite ACR guidelines should state that these recommendations are not meant for this purpose. These recommendations cannot adequately convey all uncertainties and nuances of patient care.
The American College of Rheumatology is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To develop updated guidelines for the pharmacologic management of rheumatoid arthritis.

Methods. We developed clinically relevant population, intervention, comparator, and outcomes (PICO) questions. After conducting a systematic literature review, the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach was used to rate the certainty of evidence. A voting panel comprising clinicians and patients achieved consensus on the direction (for or against) and strength (strong or conditional) of recommendations.

Results. The guideline addresses treatment with disease-modifying antirheumatic drugs (DMARDs), including conventional synthetic DMARDs, biologic DMARDs, and targeted synthetic DMARDs, use of glucocorticoids, and use of DMARDs in certain high-risk populations (i.e., those with liver disease, heart failure, lymphoproliferative disorders, previous serious infections, and nontuberculous mycobacterial lung disease). The guideline includes 44 recommendations (7 strong and 37 conditional).

Conclusion. This clinical practice guideline is intended to serve as a tool to support clinician and patient decision-making. Recommendations are not prescriptive, and individual treatment decisions should be made through a shared decision-making process based on patients' values, goals, preferences, and comorbidities.

The findings and conclusions herein are those of the authors and do not represent the official position of the Centers for Disease Control and Prevention. This study did not involve human subjects, and therefore, approval from Human Studies Committees was not required.

This article is published simultaneously in *Arthritis & Rheumatology*.

INTRODUCTION

To support high-quality clinical care, the American College of Rheumatology (ACR) regularly updates clinical practice guidelines for the management of rheumatoid arthritis (RA), with the most recent update reported in 2015 (1). The current recommendations address treatment with the following: 1) conventional synthetic disease-modifying antirheumatic drugs (csDMARDs), biologic DMARDs (bDMARDs), and targeted synthetic DMARDs (tsDMARDs); 2) glucocorticoids; and 3) use of these medications in certain high-risk populations. The use of vaccines and nonpharmacologic treatment approaches (although initially part of this project) will be covered in future ACR treatment guideline publications. For recommendations regarding pretreatment screening and routine laboratory monitoring, we refer readers to the 2008, 2012, and 2015 guidelines (1–3), with newly approved therapies following the screening process recommended for other medications in the same class. Recommendations for the perioperative management of patients undergoing elective orthopedic surgery are addressed in the 2017 guideline for perioperative management (4). For recommendations regarding reproductive health, we refer readers to the 2020 ACR Guideline for the Management of Reproductive Health in Rheumatic and Musculoskeletal Diseases (5).

In keeping with the Grading of Recommendations Assessment, Development and Evaluation [GRADE] methodology), the ACR panel developed recommendations for commonly encountered clinical scenarios (6–8). Both ***strong*** and ***conditional*** recommendations required achieving a 70% level of agreement by the voting panel. Each recommendation is qualified as being strong or conditional. In this context, strong recommendations are those for which the panel is highly confident that the recommended option favorably balances the expected benefits and risks for the majority of patients in clinical practice. In contrast, conditional recommendations are those for which the panel is less confident that the potential benefits outweigh the risks. A recommendation can be conditional either because of low or very low certainty in the evidence supporting one option over another, or because of an expectation of substantial variations in patient preferences for the options under consideration.

METHODS

This guideline follows the ACR guideline development process and ACR policy guiding the management of conflicts of interest and disclosures (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines) (6,8), which includes GRADE methodology (6,8), and abides by the AGREE Reporting Checklist to ensure the completeness and transparency of reporting in practice guidelines (9). Supplementary Appendix 1, available on the *Arthritis Care & Research* website at http://onlin

Submitted for publication September 8, 2020; accepted in revised form March 15, 2021.

elibrary.wiley.com/doi/10.1002/acr.24596/abstract), includes a detailed description of the methods. Briefly, the core leadership team drafted clinical population, intervention, comparator, and outcomes (PICO) questions. The literature review team performed systematic literature reviews for the PICO questions, selected and evaluated individual studies and graded the quality of the body of evidence available for each outcome, and produced the evidence report that summarizes these assessments (see Supplementary Appendix 2, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24596/abstract). The core team defined the critical study outcome as disease activity for most PICO questions. Because the ACR has, in a separate project, endorsed several disease activity measures for use in clinical practice, this guideline does not define levels of disease activity or the instruments a clinician should use to measure it (10). For PICO questions related to tapering, the critical outcomes were disease flare and subsequent return to the treatment target. Physical function, radiographic progression, quality of life, other patient-reported outcome measures, and adverse events were defined as important outcomes. Additional clinical outcomes were defined for PICO questions pertaining to select high-risk conditions (see Supplementary Appendix 3, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24596/abstract). When available, cost-effectiveness studies were included with the evidence reports. Cost estimates (average wholesale prices) were retrieved from Lexicomp (see Supplementary Appendix 4, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24596/abstract). The panel considered these estimates from a societal perspective, i.e., based on the list price, and not the copay.

An in-person panel of 10 patients with RA, moderated by the project's principal investigator, reviewed the evidence report (along with a summary and interpretation by the moderator) and provided patient perspectives for consideration by the voting panel. The voting panel (13 clinicians and 2 patients) reviewed the evidence reports and patient perspectives and voted on recommendation statements. Rosters of the core leadership, literature review team, and panel members are listed in Supplementary Appendix 5, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24596/abstract.

Several guiding principles, definitions, and assumptions were established a priori (Table 1). Because poor prognostic factors (11) have had less impact than other factors on prior RA treatment recommendations, they were not explicitly considered in formulating the PICO questions. However, poor prognostic factors were considered as possible influential factors in physicians' and patients' decision-making when developing recommendations. In contrast to the 2015 guideline (1), recommendations were not provided for subgroups defined by early versus late RA disease duration. This change was made because current disease activity, prior therapies used, and the presence of comorbidities were felt to be more relevant than disease duration for most treatment decisions. However, early diagnosis and treatment in RA is associated with improved outcomes and is thus an important overarching principle in its management (12). Recommendations are intended for the general RA patient population and assume that patients do not have contraindications to the options under consideration.

Table 1. Guiding principles*

RA requires early evaluation, diagnosis, and management.
Treatment decisions should follow a shared decision-making process.
Treatment decisions should be reevaluated within a minimum of 3 months based on efficacy and tolerability of the DMARD(s) chosen.
Disease activity levels refer to those calculated using RA disease activity measures endorsed by the ACR (10).
Recommendations are intended for the general RA patient population and assume that patients do not have contraindications to the options under consideration.
Recommendations are limited to DMARDs approved by the US FDA for treatment of RA. csDMARDs: hydroxychloroquine, sulfasalazine, methotrexate, leflunomide bDMARDs: TNF inhibitors (etanercept, adalimumab, infliximab, golimumab, certolizumab pegol), T cell costimulatory inhibitor (abatacept), IL-6 receptor inhibitors (tocilizumab, sarilumab), anti-CD20 antibody (rituximab)† tsDMARDs: JAK inhibitors (tofacitinib, baricitinib, upadacitinib)
Triple therapy refers to hydroxychloroquine, sulfasalazine, and either methotrexate or leflunomide.
Serious infection refers to an infection requiring intravenous antibiotics or hospitalization.
Biosimilars are considered equivalent to FDA-approved originator bDMARDs.
Recommendations referring to bDMARDs exclude rituximab unless patients have had an inadequate response to TNF inhibitors (in order to be consistent with FDA approval) or have a history of lymphoproliferative disorder for which rituximab is an approved therapy.
Treat-to-target refers to a systematic approach involving frequent monitoring of disease activity using validated instruments and modification of treatment to minimize disease activity with the goal of reaching a predefined target (low disease activity or remission).
Target refers to low disease activity or remission.
Recommendations specify that patients be at target (low disease activity or remission) for at least 6 months prior to tapering.
Dose reduction refers to lowering the dose or increasing the dosing interval of a DMARD. Gradual discontinuation of a DMARD is defined as gradually lowering the dose of a DMARD and subsequently stopping it.

* RA = rheumatoid arthritis; DMARDs = disease-modifying antirheumatic drugs; ACR = American College of Rheumatology; FDA = Food and Drug Administration; csDMARDs = conventional DMARDs; bDMARDs = biologic DMARDs; TNF = tumor necrosis factor; IL-6 = interleukin-6; tsDMARDs = targeted synthetic DMARDs.
† Anakinra was not included due to infrequent use for patients with RA.

RESULTS/RECOMMENDATIONS

The recommendations are based on a set of 81 PICO questions. The literature review initially identified 22,971 manuscripts (for the full set of PICO questions covering both pharmacologic and nonpharmacologic treatment). After excluding 18,333 titles

and abstracts, 4,038 full-text articles were screened, of which 1,392 were excluded and 2,646 were considered for the evidence report. After full-text screening, 133 manuscripts were mapped to ≥1 PICO questions addressing pharmacologic treatment (see Supplementary Appendix 6, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24596/abstract). The literature review did not identify any evidence for 41% (n = 33) of the PICO questions.

Recommendations for DMARD-naive patients with moderate-to-high disease activity (Table 2)

DMARD monotherapy

Methotrexate is strongly recommended over hydroxychloroquine or sulfasalazine for DMARD-naive patients with moderate-to-high disease activity

This recommendation is strongly in favor of methotrexate despite very low-certainty evidence for hydroxychloroquine and low-certainty evidence for sulfasalazine based on the amount of data supporting the disease-modifying properties of methotrexate monotherapy compared to hydroxychloroquine or sulfasalazine and concerns over the long-term tolerability of sulfasalazine (13,14).

Methotrexate is conditionally recommended over leflunomide for DMARD-naive patients with moderate-to-high disease activity

Despite low-certainty evidence of comparable efficacy, methotrexate is preferred over leflunomide because of the evidence supporting its value as an anchor DMARD in combination regimens. Additional advantages of methotrexate include its greater dosing flexibility and lower cost.

Methotrexate monotherapy is strongly recommended over bDMARD or tsDMARD monotherapy for DMARD-naive patients with moderate-to-high disease activity

There is low-certainty evidence suggesting superiority of tocilizumab monotherapy (15) over methotrexate monotherapy and moderate-certainty evidence suggesting greater efficacy

Table 2. Disease-modifying antirheumatic drugs (DMARDs) initiation*

Recommendations	Certainty of evidence	Based on the evidence report(s) of the following PICO(s)†	Evidence table(s), in Supp. App. 2
Initiation of treatment in DMARD-naive patients with moderate-to-high disease activity			
Methotrexate monotherapy is **strongly** recommended over:			
Hydroxychloroquine or sulfasalazine	Very low/low‡	PICO 2a.C1/C2	p. 14–5
bDMARD or tsDMARD monotherapy	Very low/moderate	PICO 5a.C1–4/C5§	p. 61–78
Combination of methotrexate plus a non–TNF inhibitor bDMARD or tsDMARD¶	Low/very low	PICO 6a.C2–4/C5§	p. 109, 117–28
Methotrexate monotherapy is **conditionally** recommended over:			
Leflunomide	Low	PICO 2a.C3	p. 18
Dual or triple csDMARD therapy¶	Moderate	PICO 4a.C1–C2	p. 46–9
Combination of methotrexate plus a TNF inhibitor¶	Low	PICO 6a.C1	p. 110
Initiation of a csDMARD without short-term (<3 months) glucocorticoids is **conditionally** recommended over initiation of a csDMARD with short-term glucocorticoids.	Very low	PICO 7a	p. 167
Initiation of a csDMARD without longer-term (≥3 months) glucocorticoids is **strongly** recommended over initiation of a csDMARD with longer-term glucocorticoids.	Moderate	PICO 8a	p. 170
Initiation of treatment in DMARD-naive patients with low disease activity			
Hydroxychloroquine is **conditionally** recommended over other csDMARDs.	Very low	PICO 1a.C1–4	p. 1–6
Sulfasalazine is **conditionally** recommended over methotrexate.	Very low	PICO 1a.C2	p. 2
Methotrexate is **conditionally** recommended over leflunomide.	Very low	PICO 1a.C3	p. 5
Initiation of treatment in csDMARD-treated, but methotrexate-naive, patients with moderate-to-high disease activity#			
Methotrexate monotherapy is **conditionally** recommended over the combination of methotrexate plus a bDMARD or tsDMARD.**	Moderate/very low	PICO 6b.C1–4/C5§	p. 136–56

* PICO = population, intervention, comparator, and outcomes; Supp. App. 2 = Supplementary Appendix 2, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24596/abstract; bDMARD = biologic DMARD; tsDMARD = targeted synthetic DMARD; TNF = tumor necrosis factor; csDMARD = conventional synthetic DMARD.
† The closest matching PICO questions to each recommendation are provided.
‡ The first certainty of evidence applies to the first listed option; the second certainty of evidence applies to the second listed option.
§ The original PICO included individual DMARDs as comparators. The recommendation considers bDMARDs as a group.
¶ The direction of the beneficial effect is in favor of the nonpreferred option.
# Other recommendations for this patient population are the same as those for DMARD-naive patients.
** The direction of the beneficial effect is in favor of the nonpreferred option. The certainty of evidence is high for the combination of methotrexate plus a TNF inhibitor and moderate for other bDMARDs.

of JAK inhibitor monotherapy over methotrexate monotherapy. The study by van Vollenhoven et al (16) was not considered by the voting panel as it was published after the evidence report was updated. However, methotrexate monotherapy is preferred because of its established efficacy and safety as a first-line DMARD and low cost. Moreover, tocilizumab and JAK inhibitors are not approved by the US Food and Drug Administration (FDA) for use in csDMARD-naive patients. Safety concerns released in early 2021 associated with JAK inhibitors (17,18) further support the recommendation of methotrexate monotherapy over tsDMARDs as initial DMARD therapy at this time.

Methotrexate monotherapy is conditionally recommended over dual or triple csDMARD therapy for DMARD-naive patients with moderate-to-high disease activity

The recommendation favors methotrexate monotherapy because the higher burden of combination therapy (e.g., multiple medications, higher cost) outweighs the moderate-quality evidence suggesting greater improvements in disease activity associated with combination csDMARDs (19). The recommendation is conditional because some patients may choose csDMARD combination therapy for an increased probability of obtaining a better response despite the added burden of taking multiple medications.

Methotrexate monotherapy is conditionally recommended over methotrexate plus a tumor necrosis factor (TNF) inhibitor for DMARD-naive patients with moderate-to-high disease activity

Despite low-certainty evidence supporting greater improvement in disease activity with methotrexate plus a TNF inhibitor, methotrexate monotherapy is preferred over the combination because many patients will reach their goal on methotrexate monotherapy and because of the additional risks of toxicity and higher costs associated with TNF inhibitors. The recommendation is conditional because some patients, especially those with poor prognostic factors, may prioritize more rapid onset of action and greater chance of improvement associated with combination therapy (20–22) over the additional risks and costs associated with initial use of methotrexate in combination with a TNF inhibitor.

Methotrexate monotherapy is strongly recommended over methotrexate plus a non–TNF inhibitor bDMARD or tsDMARD for DMARD-naive patients with moderate-to-high disease activity

There is very low-certainty evidence supporting the superiority of methotrexate plus a non–TNF inhibitor bDMARD or tsDMARD over methotrexate monotherapy in DMARD-naive patients; thus, methotrexate monotherapy is strongly preferred given the lack of proven benefit and additional risks and costs associated with the addition of a non–TNF inhibitor bDMARD or tsDMARD in this patient population.

Glucocorticoids

Initiation of a csDMARD without short-term (<3 months) glucocorticoids is conditionally recommended over initiation of a csDMARD with short-term glucocorticoids for DMARD-naive patients with moderate-to-high disease activity

While the voting panel agreed that glucocorticoids should not be systematically prescribed, the recommendation is conditional because all members acknowledged that short-term glucocorticoids are frequently necessary to alleviate symptoms prior to the onset of action of DMARDs. Treatment with glucocorticoids should be limited to the lowest effective dose for the shortest duration possible. The toxicity associated with glucocorticoids was judged to outweigh potential benefits.

Initiation of a csDMARD without longer-term (≥3 months) glucocorticoids is strongly recommended over initiation of a csDMARD with longer-term glucocorticoids for DMARD-naive patients with moderate-to-high disease activity

Although some patients may require longer-term glucocorticoids, this strong recommendation *against* longer-term glucocorticoid therapy is made because of its significant toxicity.

Recommendations for DMARD-naive patients with low disease activity (Table 2)

Hydroxychloroquine is conditionally recommended over other csDMARDs, sulfasalazine is conditionally recommended over methotrexate, and methotrexate is conditionally recommended over leflunomide for DMARD-naive patients with low disease activity

Hydroxychloroquine is conditionally recommended over other csDMARDs because it is better tolerated and has a more favorable risk profile in patients with RA. Sulfasalazine is recommended over methotrexate because it is less immunosuppressive, and the patient panel felt that many patients with low disease activity would prefer to avoid the side effects associated with methotrexate. The recommendations are conditional because methotrexate may be the preferred initial therapy in patients at the higher end of the low disease activity range and in those with poor prognostic factors (11). Methotrexate is recommended over leflunomide because of its greater dosing flexibility and lower cost.

Recommendation for patients who have been treated with csDMARDs, excluding methotrexate, and who have moderate-to-high disease activity (Table 2)

Recommendations are the same as for DMARD-naive patients except for this population. The strength of the following recommendation is conditional for all bDMARDs and tsDMARDs.

Methotrexate monotherapy is conditionally recommended over the combination of methotrexate plus a bDMARD or tsDMARD

The recommendation is conditional because the voting panel thought that some patients who have already had persistent disease activity despite use of ≥1 csDMARD will prefer combination treatment for a more rapid response.

Recommendations for administration of methotrexate (Table 3)

Oral methotrexate is conditionally recommended over subcutaneous methotrexate for patients initiating methotrexate

Oral administration is preferred, despite moderate evidence suggesting superior efficacy of subcutaneous injections, due to the ease of oral administration and similar bioavailability at typical starting doses (23).

Initiation/titration of methotrexate to a weekly dose of at least 15 mg within 4 to 6 weeks is conditionally recommended over initiation/titration to a weekly dose of <15 mg

The recommendation is conditional because there are few studies comparing different dosing strategies and wide variation in physician and patient preferences regarding the tradeoff between the increased efficacy and risks of toxicity associated with higher starting doses. This recommendation refers only to the initial prescribing of methotrexate and is not meant to limit further dose escalation, which often provides additional efficacy (24).

A split dose of oral methotrexate over 24 hours or weekly subcutaneous injections, and/or an increased dose of folic/folinic acid, is conditionally recommended over switching to alternative DMARD(s) for patients not tolerating oral weekly methotrexate

Despite the very low certainty of evidence supporting these strategies for alleviating side effects related to methotrexate, split dosing, changing to the subcutaneous route of administration, and increased doses of folic/folinic acid are the preferred initial strategies over switching to another DMARD because of the efficacy, long-term safety, and low costs associated with methotrexate. The recommendation is conditional because patient preferences play an important role in the decision whether to continue methotrexate or switch to other DMARDs.

Switching to subcutaneous methotrexate is conditionally recommended over the addition of/switching to alternative DMARD(s) for patients taking oral methotrexate who are not at target

This recommendation is consistent with the voting panel's overarching principle of maximizing use of methotrexate prior to switching/adding DMARDs. However, there are no data comparing outcomes in patients who switch to subcutaneous methotrexate versus another treatment strategy that includes other DMARDs. The recommendation is conditional because patient preferences and the magnitude of previous response to methotrexate play an important role in this decision.

Table 3. Methotrexate administration*

Recommendations	Certainty of evidence	Based on the evidence report(s) of the following PICO(s)	Evidence table(s), in Supp. App. 2
Oral methotrexate is **conditionally** recommended over subcutaneous methotrexate for patients initiating methotrexate.	Moderate	PICO 9	p. 181
Initiation/titration of methotrexate to a weekly dose of at least 15 mg within 4 to 6 weeks is **conditionally** recommended over initiation/titration to a weekly dose of <15 mg.†	Moderate/ very low‡	PICO 10.C1–C3	p. 184–5
A split dose of oral methotrexate over 24 hours or subcutaneous injections, and/or an increased dose of folic/folinic acid, is **conditionally** recommended over switching to alternative DMARD(s) for patients not tolerating oral weekly methotrexate.	Very low	PICO 16 and PICO 15	p. 206–10
Switching to subcutaneous methotrexate is **conditionally** recommended over the addition of/switching to alternative DMARD(s) for patients taking oral methotrexate who are not at target.	Very low	PICO 18	p. 235

* PICO = population, intervention, comparator, and outcomes; Supp. App. 2 = Supplementary Appendix 2, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24596/abstract; DMARD = disease-modifying antirheumatic drug.
† This recommendation refers only to the initial prescribing of methotrexate and is not meant to limit further dose escalation, which often provides additional efficacy.
‡ The first certainty of evidence applies to the first listed option; the second certainty of evidence applies to the second option.

Recommendations for treatment modification in patients treated with DMARDs who are not at target (Table 4)

Treat-to-target

A treat-to-target approach is strongly recommended over usual care for patients who have not been previously treated with bDMARDs or tsDMARDs

This recommendation applies to dose optimization of methotrexate and to the subsequent addition of DMARDs when required. The recommendation is strong despite low-certainty evidence because of the recognized importance of systematic monitoring and adjustment of treatment to minimize inflammation to prevent joint damage, as well as other long-term sequelae including cardiovascular disease and osteoporosis.

A treat-to-target approach is conditionally recommended over usual care for patients who have had an inadequate response to bDMARDs or tsDMARDs

The recommendation is conditional because of the uncertain incremental benefits of treat-to-target over usual care in this patient population. In this context, usual care refers to commonly employed practice patterns, i.e., adjustment of treatment based on shared decision-making, albeit typically without systematic monitoring of disease activity using validated measures to reach a predefined target. Moreover, 1) the number of remaining available treatment options, 2) the impact of noninflammatory causes of pain, comorbidities, and/or damage on the accuracy of validated disease activity assessments, and 3) the patient's threshold for changing medications may have a more significant influence on the decision to follow a treat-to-target approach in this population compared to patients who are bDMARD- and tsDMARD-naive.

A minimal initial treatment goal of low disease activity is conditionally recommended over a goal of remission

An initial target of low disease activity is preferred because remission by established criteria may not be achievable for many patients (25). In addition, the patient panel emphasized that failure to reach a specified target may be disheartening and stressful for some patients. They emphasized that it would be preferable to *initially* aim for low disease activity and *subsequently* consider a goal of remission. However, treatment goals should be systematically reassessed over time and individualized to each patient to ensure that remission is targeted when possible. The recommendation is conditional because remission is a reasonable initial goal for patients with early disease and minimal exposure to bDMARDs and tsDMARDs, and patient preferences play a significant role in this decision.

Modification of DMARD(s)

Addition of a bDMARD or tsDMARD is conditionally recommended over triple therapy (i.e., addition of sulfasalazine and hydroxychloroquine) for patients taking maximally tolerated doses of methotrexate who are not at target

The panel vigorously debated whether to recommend addition of a bDMARD or tsDMARD versus sulfasalazine and

Table 4. Treatment modification*

Recommendations	Certainty of evidence	Based on the evidence report(s) of the following PICO(s)	Evidence table(s), in Supp. App. 2
A TTT approach is **strongly** recommended over usual care for patients who have not been previously treated with bDMARDs or tsDMARDs.	Low	PICO 12.a	p. 191
A TTT approach is **conditionally** recommended over usual care for patients who have had an inadequate response to bDMARDs or tsDMARDs.	Very low	PICO 12.b	p. 199
A minimal initial treatment goal of low disease activity is **conditionally** recommended over a goal of remission.	Low	PICO 13	p. 201
Addition of a bDMARD or tsDMARD is **conditionally** recommended over triple therapy for patients taking maximally tolerated doses of methotrexate who are not at target.	Very low	PICO 19.C2–C6†	p. 240–1
Switching to a bDMARD or tsDMARD of a different class is **conditionally** recommended over switching to a bDMARD or tsDMARD belonging to the same class for patients taking a bDMARD or tsDMARD who are not at target.	Very low	PICO 24–27†	p. 293–338
Addition of/switching to DMARDs is **conditionally** recommended over continuation of glucocorticoids for patients taking glucocorticoids to remain at target.	Very low	PICO 23	p. 292
Addition of/switching to DMARDs (with or without IA glucocorticoids) is **conditionally** recommended over the use of IA glucocorticoids alone for patients taking DMARDs who are not at target.	Very low	PICO 28.C1–C2	p. 339–40

* PICO = population, intervention, comparator, and outcomes; Supp. App. 2 = Supplementary Appendix 2, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24596/abstract; TTT = treat-to-target; bDMARDs = biologic disease-modifying antirheumatic drugs; tsDMARDs = targeted synthetic DMARDs; IA = intraarticular.
† The original PICO included individual DMARDs as comparators. The recommendation considers bDMARDs as a group.

hydroxychloroquine (triple therapy) for patients with an inadequate response to methotrexate monotherapy in view of very low-certainty evidence favoring bDMARDs or tsDMARDs, randomized controlled trials demonstrating equivalent long-term outcomes across both treatment strategies, and significantly less societal cost associated with triple therapy (26–29). Addition of a bDMARD or tsDMARD was ultimately preferred because the patient panel strongly prioritized maximizing improvement as quickly as possible. In addition, both the patient and voting panels valued the greater persistence of methotrexate plus a bDMARD or tsDMARD compared to triple therapy (defined in Table 1) (13,30). The recommendations from these studies (13,31) are conditional because triple therapy may be preferred in lower resource settings as well as in patients with specific comorbidities for whom triple therapy may be associated with significantly less risk of adverse events. This choice is highly preference sensitive, and decisions on how best to escalate care should incorporate patients' preferences. There is no current recommendation for a bDMARD versus a tsDMARD when adjusting treatment; however, the voting panel acknowledged that safety data released in early 2021 (17,18) may require a modification of this recommendation when peer-reviewed results are published.

Switching to a bDMARD or tsDMARD of a different class is conditionally recommended over switching to a bDMARD or tsDMARD belonging to the same class for patients taking a bDMARD or tsDMARD who are not at target

The recommendation is based on very low-certainty evidence supporting greater improvement in disease activity and drug survival among patients switching classes. The recommendation is conditional because patient and physician preferences are likely to vary based on prior experiences with specific DMARDs.

Use of glucocorticoids

Addition of/switching to DMARDs is conditionally recommended over continuation of glucocorticoids for patients taking glucocorticoids to remain at target

This recommendation assumes that improved disease control with DMARDs should allow less use of glucocorticoids. The recommendation is conditional because the continued use of glucocorticoids may be required for patients who do not respond to DMARDs even after maximizing methotrexate dosage and switching DMARD classes.

Addition of/switching to DMARDs (with or without intraarticular [IA] glucocorticoids) is conditionally recommended over the use of IA glucocorticoids alone for patients taking DMARDs who are not at target

This recommendation was based on the premise that DMARDs should be adjusted to reduce disease activity, irrespective of treatment with IA glucocorticoids. The recommendation is conditional because patients may choose to defer adding/switching DMARDs if they obtain relief from IA injection(s).

Recommendations for tapering/discontinuing DMARDs (Table 5)

Because of the moderate-to-high risk for flare and the potential for irreversible long-term damage associated with stopping all DMARDs, the following recommendations presume that patients maintain a therapeutic dose of at least 1 DMARD. In addition, the recommendations specify that patients be at target (low disease activity or remission) for at least 6 months

Table 5. Tapering disease-modifying antirheumatic drugs (DMARDs)*

Recommendations	Certainty of evidence	Based on the evidence report(s) of the following PICO(s)	Evidence table(s), in Supp. App. 2
Continuation of all DMARDs at their current dose is **conditionally** recommended over a dose reduction of a DMARD.	Low	PICO 54.a	p. 381
Dose reduction is **conditionally** recommended over gradual discontinuation of a DMARD.	Low	PICO 52.C2 and PICO 53. C2	p. 351–5, p. 372–6
Gradual discontinuation is **conditionally** recommended over abrupt discontinuation of a DMARD.	Low	PICO 52.C1 and PICO 53.C1	p. 351, 372
Gradual discontinuation of sulfasalazine is **conditionally** recommended over gradual discontinuation of hydroxychloroquine for patients taking triple therapy who wish to discontinue a DMARD.	Very low	PICO 58	p. 400
Gradual discontinuation of methotrexate is **conditionally** recommended over gradual discontinuation of the bDMARD or tsDMARD for patients taking methotrexate plus a bDMARD or tsDMARD who wish to discontinue a DMARD.	Very low	PICO 59.C1	p. 401

* PICO = population, intervention, comparator, and outcomes; Supp. App. 2 = Supplementary Appendix 2, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24596/abstract; bDMARD = biologic DMARD; tsDMARD = targeted synthetic DMARD.

prior to tapering. Patients in remission for <6 months should not routinely be considered for dose reduction or withdrawal. Although the optimal time at target prior to tapering has not been established, the voting panel considered 6 months to be a reasonable minimal length of time to ensure stable disease control. "Dose reduction" refers to lowering the dose or increasing the dosing interval of a DMARD. "Gradual discontinuation" denotes gradually lowering the dose of a DMARD and subsequently stopping it.

Continuation of all DMARDs at their current dose is conditionally recommended over a dose reduction of a DMARD, dose reduction is conditionally recommended over gradual discontinuation of a DMARD, and gradual discontinuation is conditionally recommended over abrupt discontinuation of a DMARD for patients who are at target for at least 6 months

These recommendations are based on studies demonstrating a higher risk of flare in patients who are 1) lowering the dose of a DMARD versus continuing DMARDs at the same dose, and 2) abruptly versus gradually discontinuing a DMARD (32–36). The recommendations are conditional because patient and physician preferences are expected to vary.

Gradual discontinuation of sulfasalazine is conditionally recommended over gradual discontinuation of hydroxychloroquine for patients taking triple therapy who wish to discontinue a DMARD

Gradually discontinuing sulfasalazine is recommended because of its poorer treatment persistence due to adverse events (14). The recommendation is conditional because patient and physician preferences are expected to vary.

Gradual discontinuation of methotrexate is conditionally recommended over gradual discontinuation of the bDMARD or tsDMARD for patients taking methotrexate plus a bDMARD or tsDMARD who wish to discontinue a DMARD

In the absence of direct evidence, gradually discontinuing methotrexate is preferred because a bDMARD or tsDMARD is typically added following an inadequate response to methotrexate. Thus, the continued use of the bDMARD or tsDMARD is more likely to maintain disease control than the continued use of methotrexate. The recommendation is conditional because gradual discontinuation of the bDMARD or tsDMARD may be favored depending on comorbidities, risk for infection, cost concerns, as well as patient and clinician preferences. The voting panel cautioned that many patients treated with certain monoclonal antibodies may require ongoing treatment with methotrexate to prevent the formation of antidrug antibodies (37).

Recommendations for specific patient populations (Table 6)

Subcutaneous nodules

Methotrexate is conditionally recommended over alternative DMARDs for patients with subcutaneous nodules who have moderate-to-high disease activity

Switching to a non-methotrexate DMARD is conditionally recommended over continuation of methotrexate for patients taking methotrexate with progressive subcutaneous nodules

While accelerated nodulosis has been observed in patients starting methotrexate (38), there are no studies examining comparative strategies for patients with stable or progressive subcutaneous nodules. The preceding 2 recommendations are conditional because patient and clinician preferences are expected to vary. The recommendation to switch is based on the premise that methotrexate is a contributing factor to progressive nodulosis.

Pulmonary disease

Methotrexate is conditionally recommended over alternative DMARDs for the treatment of inflammatory arthritis for patients with clinically diagnosed mild and stable airway or parenchymal lung disease, or incidental disease detected on imaging, who have moderate-to-high disease activity

Studies indicate that preexisting lung disease is a risk factor for methotrexate-related pneumonitis (39,40). However, the overall risk of worsening lung disease attributable to methotrexate is uncertain, and alternative DMARDs have also been associated with lung disease (41–45). The recommendation is in favor of methotrexate because of its important role as an anchor treatment in RA and the lack of alternatives with similar efficacy and/or superior long-term safety profiles. The recommendation is conditional because some clinicians (rheumatologists and pulmonologists) and patients will prefer an alternative option rather than accept any additional risk of lung toxicity. Patients with preexisting lung disease should be informed of their increased risk of methotrexate pneumonitis prior to initiating treatment with methotrexate.

Table 6. Specific patient populations*

Recommendations	Certainty of evidence	Based on the evidence report(s) of the following PICO(s)	Evidence table(s), in Supp. App. 2
Subcutaneous nodules			
Methotrexate is **conditionally** recommended over alternative DMARDs for patients with subcutaneous nodules who have moderate-to-high disease activity.	Very low	PICO 64	p. 427
Switching to a non-methotrexate DMARD is **conditionally** recommended over continuation of methotrexate for patients taking methotrexate with progressive subcutaneous nodules.	Very low	PICO 65	p. 428
Pulmonary disease			
Methotrexate is **conditionally** recommended over alternative DMARDs for the treatment of inflammatory arthritis for patients with clinically diagnosed mild and stable airway or parenchymal lung disease who have moderate-to-high disease activity.	Very low	PICO 67	p. 430
Heart failure			
Addition of a non–TNF inhibitor bDMARD or tsDMARD is **conditionally** recommended over addition of a TNF inhibitor for patients with NYHA class III or IV heart failure and an inadequate response to csDMARDs.	Very low	PICO 70	p. 435
Switching to a non–TNF inhibitor bDMARD or tsDMARD is **conditionally** recommended over continuation of a TNF inhibitor for patients taking a TNF inhibitor who develop heart failure.	Very low	PICO 71	p. 436
Lymphoproliferative disorder			
Rituximab is **conditionally** recommended over other DMARDs for patients who have a previous lymphoproliferative disorder for which rituximab is an approved treatment and who have moderate-to-high disease activity.	Very low	PICO 75 and PICO 76	p. 446–7
Hepatitis B infection			
Prophylactic antiviral therapy is **strongly** recommended over frequent monitoring alone for patients initiating rituximab who are hepatitis B core antibody positive (regardless of hepatitis B surface antigen status).	Very low	PICO 82	p. 459
Prophylactic antiviral therapy is **strongly** recommended over frequent monitoring alone for patients initiating any bDMARD or tsDMARD who are hepatitis B core antibody positive and hepatitis B surface antigen positive.	Very low	PICO 83	p. 464
Frequent monitoring alone is **conditionally** recommended over prophylactic antiviral therapy for patients initiating a bDMARD other than rituximab or a tsDMARD who are hepatitis B core antibody positive and hepatitis B surface antigen negative.	Very low	PICO 84	p. 471
Nonalcoholic fatty liver disease			
Methotrexate is **conditionally** recommended over alternative DMARDs for DMARD-naive patients with nonalcoholic fatty liver disease, normal liver enzymes and liver function tests, and no evidence of advanced liver fibrosis who have moderate-to high disease activity.	Very low	PICO 87	p. 489
Persistent hypogammaglobulinemia without infection			
In the setting of persistent hypogammaglobulinemia without infection, continuation of rituximab therapy for patients at target is **conditionally** recommended over switching to a different bDMARD or tsDMARD.	Very low	PICO 66	p. 429
Previous serious infection			
Addition of csDMARDs is **conditionally** recommended over addition of a bDMARD or tsDMARD for patients with a serious infection within the previous 12 months who have moderate-to-high disease activity despite csDMARD monotherapy.	Very low	PICO 88	p. 490
Addition of/switching to DMARDs is **conditionally** recommended over initiation/dose escalation of glucocorticoids for patients with a serious infection within the previous 12 months who have moderate-to-high disease activity.	Very low	PICO 90 and PICO 91	p. 496–7
Nontuberculous mycobacterial lung disease			
Use of the lowest possible dose of glucocorticoids (discontinuation if possible) is **conditionally** recommended over continuation of glucocorticoids for patients with nontuberculous mycobacterial lung disease.	Very low	No relevant PICO	
Addition of csDMARDs is **conditionally** recommended over addition of a bDMARD or tsDMARD for patients with nontuberculous mycobacterial lung disease who have moderate-to-high disease activity despite csDMARD monotherapy.	Very low	PICO 92	p. 498
Abatacept is **conditionally** recommended over other bDMARDs and tsDMARDs for patients with nontuberculous mycobacterial lung disease who have moderate-to-high disease activity despite csDMARDs.	Very low	PICO 93	p. 499

* PICO = population, intervention, comparator, and outcomes; Supp. App. 2 = Supplementary Appendix 2, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24596/abstract; DMARDs = disease-modifying antirheumatic drugs; TNF = tumor necrosis factor; bDMARD = biologic DMARD; tsDMARD = targeted synthetic DMARD; NYHA = New York Heart Association; csDMARDs = conventional synthetic DMARDs.

Table 7. Key clinical questions requiring further research*

Methotrexate administration
At what dose and route of administration should methotrexate be started?
Does switching to non-methotrexate DMARDs improve tolerability over increasing the dose of folic acid, or using folinic acid or using split dose or subcutaneous dosing, for RA patients with side effects when taking methotrexate?
TTT
What is the efficacy of TTT in different patient populations (early versus late, bDMARD- or tsDMARD-exposed, elderly-onset, comorbidities)?
What is the optimal target and method of assessment of disease activity for TTT in different populations?
Comparative effectiveness/safety
What is the comparative effectiveness/safety between bDMARDs and tsDMARDs?
What is the comparative effectiveness/safety between adding bDMARDs or tsDMARDs to methotrexate and switching to bDMARD or tsDMARD monotherapy?
What is the comparative effectiveness/safety between TTT by maximizing use of methotrexate (i.e., escalating dose via subcutaneous route) and adding/switching to bDMARD or tsDMARD monotherapy?
When, which, and how should DMARDs be tapered/discontinued?
Do clinical or biologic markers predict a differential response to DMARDs?
Comorbidities
What is the effectiveness/safety of alternative treatment strategies in RA patients with clinical lung disease or NAFLD?
Which DMARDs can be initiated or continued after receiving checkpoint inhibitor therapy?
Which DMARDs should be used in patients with solid malignancies, including skin cancer?
Is there a time frame before which DMARDs can be started/resumed in patients with concomitant solid malignancies?

* DMARDs = biologic disease-modifying antirheumatic drugs; RA = rheumatoid arthritis; TTT = treat-to-target; bDMARD = biologic DMARD; tsDMARD = targeted synthetic DMARD; NAFLD = nonalcoholic fatty liver disease.

Heart failure

Addition of a non–TNF inhibitor bDMARD or tsDMARD is conditionally recommended over addition of a TNF inhibitor for patients with New York Heart Association (NYHA) class III or IV heart failure and an inadequate response to csDMARDs

Switching to a non–TNF inhibitor bDMARD or tsDMARD is conditionally recommended over continuation of a TNF inhibitor for patients taking a TNF inhibitor who develop heart failure

These recommendations are based on the risk of worsening heart failure observed in randomized clinical trials of TNF inhibitors in patients with NYHA class III or IV heart failure without RA (46,47). Both recommendations are conditional because of the very low-certainty evidence supporting these PICO questions.

Lymphoproliferative disorder

Rituximab is conditionally recommended over other DMARDs for patients who have a previous lymphoproliferative disorder for which rituximab is an approved treatment and who have moderate-to-high disease activity

Rituximab is preferred over other DMARDs, regardless of previous DMARD experience, because it would not be expected to increase the risk of recurrence or worsening of these lymphoproliferative disorders. The recommendation is conditional because of the very low-certainty evidence supporting this PICO question.

Hepatitis B infection

Prophylactic antiviral therapy is strongly recommended over frequent monitoring of viral load and liver enzymes alone for patients initiating rituximab who are hepatitis B core antibody positive (regardless of hepatitis B surface antigen status)

Prophylactic antiviral therapy is strongly recommended over frequent monitoring alone for patients initiating any bDMARD or tsDMARD who are hepatitis B core antibody positive and hepatitis B surface antigen positive

Frequent monitoring alone of viral load and liver enzymes is conditionally recommended over prophylactic antiviral therapy for patients initiating a bDMARD other than rituximab or a tsDMARD who are hepatitis B core antibody positive and hepatitis B surface antigen negative

These recommendations were made based on the risk of hepatitis B reactivation due to core antibody and surface antigen status and the specific DMARD being initiated and are consistent with the updated American Association for the Study of Liver Diseases guidance (48). Patients at risk for hepatitis B reactivation should be comanaged with a hepatologist. The third recommendation is conditional because it is less certain whether the benefit of prophylactic antiviral therapy outweighs the risks and cost of this treatment in the specified patient population.

Nonalcoholic fatty liver disease (NAFLD)

Methotrexate is conditionally recommended over alternative DMARDs for DMARD-naive patients with NAFLD, normal liver enzymes and liver function tests, and no evidence of advanced liver fibrosis who have moderate-to-high disease activity

Given the concerns about the risk of hepatotoxicity associated with methotrexate therapy in patients with NAFLD, use of methotrexate should be restricted to patients with normal liver enzymes and liver function tests and without evidence of liver disease or liver fibrosis (Stage 3 or 4). Noninvasive testing to diagnose and stage liver fibrosis as well as consultation with a gastroenterologist or hepatologist should be considered in patients prior to initiating methotrexate (49). In addition, more frequent monitoring should be performed in this patient population (every 4 to 8 weeks). The recommendation is conditional because patients' and clinicians' risk tolerance varies.

Persistent hypogammaglobulinemia without infection

In the setting of persistent hypogammaglobulinemia without infection, continuation of rituximab therapy for patients at target is conditionally recommended over switching to a different bDMARD or tsDMARD

Continuing rituximab in patients who are at target is preferred because of the uncertain clinical significance of hypogammaglobulinemia in patients without infection. Although an increased risk of infection has been described in RA patients with hypogammaglobulinemia, it is not known if a switch in DMARDs in patients who are at target is more effective in lowering infection risk while maintaining disease control than continuation of rituximab. The recommendation is conditional because physician and patient risk tolerance is likely to vary depending on the degree of hypogammaglobulinemia and patient-specific risk factors for infection.

Previous serious infection

Addition of csDMARDs is conditionally recommended over addition of a bDMARD or tsDMARD for patients with a serious infection within the previous 12 months who have moderate-to-high disease activity despite csDMARD monotherapy

This conditional recommendation is made based on observational data suggesting a lower risk of infection associated with combination csDMARDs (dual or triple therapy) compared to bDMARDs or tsDMARDs (50). Some clinicians may prefer csDMARDs even if the serious infection occurred >12 months prior to considering a change.

Addition of/switching to DMARDs is conditionally recommended over initiation/dose escalation of glucocorticoids for patients with a serious infection within the previous 12 months who have moderate-to-high disease activity

This conditional recommendation is made based on observational studies suggesting a strong association between dose and duration of glucocorticoids with the risk of serious infection (51–53).

Nontuberculous mycobacterial (NTM) lung disease

Given the variability of NTM lung disease severity and response to treatment, patients should be closely comanaged with an infectious disease or pulmonary specialist.

Use of the lowest possible dose of glucocorticoids (discontinuation if possible) is conditionally recommended over continuation of glucocorticoids without dose modification for patients with NTM lung disease

This recommendation is based on studies suggesting an increased risk of NTM lung disease in patients receiving either inhaled or oral glucocorticoids (54,55).

Addition of csDMARDs is conditionally recommended over addition of a bDMARD or tsDMARD for patients with NTM lung disease who have moderate-to-high disease activity despite csDMARD monotherapy

This recommendation is based on the lower expected risk of NTM lung disease associated with csDMARDs compared to bDMARDs and tsDMARDs (56).

Abatacept is conditionally recommended over other bDMARDs and tsDMARDs for patients with NTM lung disease who have moderate-to-high disease activity despite csDMARDs

Abatacept is conditionally recommended over other bDMARDs and tsDMARDs based on population data extrapolated from studies on tuberculosis (57). There is considerable uncertainty regarding the risk of mycobacterial infections associated with non–TNF inhibitor bDMARDs and tsDMARDs; however, TNF inhibitors are associated with increased rates of mycobacterial infections and should be avoided (58).

The preceding 3 recommendations are conditional because of the very low-certainty evidence supporting the analysis of the differences in treatment outcomes posed by these PICO questions.

DISCUSSION

The ACR guidelines were developed to provide clinicians with recommendations for decisions frequently faced in clinical practice. Several new topics are included in this update, including recommendations for administration of methotrexate, use of methotrexate in patients with subcutaneous nodules, pulmonary disease, and NAFLD, use of rituximab in patients with hypogammaglobulinemia, and treatment of RA in patients with NTM lung disease. Areas covered in the 2015 guidelines that are not covered in this update include recommendations for patients with hepatitis C and solid malignancies. The panel did not vote on specific recommendations for patients with hepatitis C because curative antiviral therapy is now widely available. The panel did deliberate over PICO questions related to use of DMARDs in patients with solid malignancies. However, given the changing landscape of personalized treatments for many solid malignancies, the voting panel felt that a generalized recommendation was not possible.

On February 4, 2021, the FDA released a Drug Safety Alert noting a possible increased risk of major cardiovascular events and malignancies (excluding non-melanoma skin cancer) in patients with RA (over the age of 50 years with at least 1 risk factor for cardiovascular disease) participating in a randomized controlled trial designed to compare the safety of tofacitinib to adalimumab (18). Recommendations will be reviewed once peer-reviewed results are published. Rapidly evolving comparative effectiveness and safety signals associated with JAK inhibitors highlight the need to engage in a shared decision-making process when adjusting DMARDs (16,59). In addition, although previous recommendations cautioned against the use of TNF inhibitors in patients with skin cancer (1), the results of more recently published studies examining specific DMARD-related risks of non-melanoma skin cancer and melanoma do not support making a definite recommendation for or against specific DMARDs (60,61).

The panel also considered PICO questions related to current use of checkpoint inhibitor therapy, but the variability in current practice patterns and differences in treatment for specific cancer types precluded the development of specific recommendations for patients who are candidates for, or are currently receiving checkpoint inhibitor therapy. We anticipate that additional recommendations for patients with systemic rheumatic diseases and solid malignancies will be developed as further data become available. There were vigorous discussions pertaining to recommendations for specific DMARDs in patients with moderate-to-high disease activity despite csDMARDs and with a history of serious infection. However, the evidence was insufficient to support a recommendation. Future studies (using large registries and network meta-analyses) are needed to support specific recommendations for this patient population.

The recommendation statements in this update are not directly comparable to the ACR 2015 guidelines (1) because they do not retain the early versus established RA subgroups. Nevertheless, there are some notable differences. First, the 2015 guidelines recommend csDMARD monotherapy, preferably with methotrexate, for patients with both low and moderate/high disease activity, whereas this update recommends an initial trial of hydroxychloroquine or sulfasalazine for those with low disease activity. Second, the 2015 guidelines recommended DMARD tapering for patients who are in remission. In this update, tapering recommendations are made for patients who are in low disease activity or remission in the face of a paucity of data about when and how best to taper. The panel recommended that careful tapering might be considered if the patient wishes to cut back on their use of DMARDs. However, patients should be closely evaluated during any taper, and if a flare occurs, the prior regimen should be reinstituted promptly. Last, this update includes several recommendations *against* the use of glucocorticoid therapy. These recommendations were made in recognition of the frequent difficulty tapering glucocorticoids leading to undesirable prolonged use and the increasing evidence of the negative impact of glucocorticoids on long-term patient outcomes, including risk for infection, osteoporosis, and cardiovascular disease, in RA and other rheumatic diseases (62–65).

While consensus was easily reached on the majority of statements, 2 issues required prolonged discussion and debate. The decision on whether patients with an inadequate response to methotrexate should escalate to a bDMARD, tsDMARD, or triple therapy engendered much discussion with contrasting points of view. In the end, a recommendation was made in favor of a bDMARD or tsDMARD because of the more rapid onset of benefit and concerns related to the poor tolerability and durability of triple therapy in real-world practice (13,14). In particular, the patient panel highlighted the importance of a rapid onset of benefit after already having had an inadequate response to methotrexate. The conditional recommendation to initiate methotrexate therapy for patients with preexisting mild, stable lung disease was also rigorously debated. While minimizing the risk of toxicity is paramount, the voting panel favored a conditional recommendation to initiate methotrexate therapy in this clinical setting because of the vital role of this DMARD in the overall treatment of RA and lack of other comparable therapies without pulmonary risks.

Members of the voting panel agreed with the patient panel on the direction and strength of all but 2 recommendations. Patients were in favor of initial treatment with combination csDMARDs over methotrexate monotherapy because they placed greater value on the incremental benefits associated with combination therapy compared to clinicians. This preference was also stated in the 2015 guidelines (66). Patients also strongly preferred

discontinuing over a dose reduction of a DMARD whenever possible, whereas most clinicians on the voting panel preferred dose reduction. This discordance reflects patient preference to minimize use of medications once they reach target versus physician preference to minimize flare. However, both the patient and voting panel stressed the variability in patient preferences for tapering. These differences reinforce the importance of using a shared decision-making approach in RA.

When clinically relevant, recommendations specify the level of disease activity in the patient population (Table 1). However, evidence tables include pooled data from studies that often use different measures of disease activity; thus, specific definitions of low versus moderate-to-high disease activity are not provided for specific recommendations. Despite the large body of literature related to pharmacologic treatments for RA, the review team did not identify high-certainty evidence for many of the questions addressed. This discrepancy is due to the differences between clinically important PICO questions and the specific objectives of clinical trials. For example, few studies have examined how to best dose and administer methotrexate, the most effective and safe use of DMARDs in high-risk populations, and the risk–benefit tradeoffs associated with glucocorticoid use. Moreover, many trials could not be matched to specific PICO questions because of differences between the trials and the PICO questions' specified study populations and treatment comparisons. Thus, many recommendations are based largely on very low-certainty or low-certainty evidence. Incorporating medical evidence and expert input and consensus into clinical guidelines is core to the GRADE process and strengthens recommendations, particularly when there is limited evidence. Important gaps in knowledge are described in Table 7.

In summary, this update includes recommendations related to initiation and adjustment of DMARD therapy in patients with RA. It also emphasizes the importance of minimizing use of glucocorticoids. It is expected that additional data may modify the direction and/or strength of specific recommendations. The ACR will update the recommendations and answer these and other questions as new data are published.

ACKNOWLEDGMENTS

We thank Stanley B. Cohen, MD, for his contributions during the scoping phase of the project. We thank Cassandra Calabrese, DO, Leonard Calabrese, DO, Joseph Lim, MD, Danielle Antin-Ozerkis, MD, Marcus R. Pereira, MD, MPH, Jason E. Stout, MD, MHS, and Kevin Winthrop, MD, MPH, for their expert input as the voting panel considered recommendations related to comorbidities. We thank Nancy Baker, ScD, MPH, OTR/l, and Daniel White, PT, ScD, MSc, for their contributions during the scoping phase of the project, as well as their input during early deliberations by the voting panel. We thank the patients who (along with authors Kristine Carandang, PhD, OTR/L, and Shilpa Venkatachalam, PhD) participated in the patient panel meeting: Susan Campbell, Rachelle Crow-Hercher, MEd, Doug Davis, Sidney Harper, Faith Powell, Zenethia Roberts, Mary Turner, and C. Whitney White, PharmD. We thank the ACR staff, including Regina Parker for assistance in organizing the face-to-face meeting and coordinating the administrative aspects of the project, Robin Lane for assistance in manuscript preparation, and Jocelyn Givens for assistance with recruitment for the patient panel. We thank Janet Waters and Janet Joyce for their assistance in developing the literature search strategy, as well as performing the initial literature search and update searches.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be submitted for publication. Dr. Fraenkel had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study conception and design. Fraenkel, Bathon, England, St.Clair, Deane, Genovese, Kerr, Kremer, Sparks, Venkatachalam, Weinblatt, George, Johnson, Turner, Yaacoub, Akl.

Acquisition of data. Fraenkel, Bathon, England, St.Clair, Carandang, Deane, Genovese, Kerr, Kremer, J. Singh, Sparks, Al-Gibbawi, Baker, Barton, Cappelli, George, Johnson, Kahale, Karam, Khamis, Navarro-Millán, Mirza, Schwab, N. Singh, Turgunbaev, Turner, Yaacoub, Akl.

Analysis and interpretation of data. Fraenkel, Bathon, England, St.Clair, Arayssi, Deane, Genovese, Huston, Kerr, Kremer, Nakamura, Russell, J. Singh, Smith, Sparks, Venkatachalam, Weinblatt, Al-Gibbawi, Barbour, Barton, Chamseddine, Johnson, Kahale, Karam, Khamis, Navarro-Millán, Mirza, Schwab, N. Singh, Turgunbaev, Yaacoub, Akl.

ADDITIONAL DISCLOSURES

Author Genovese was employed by Stanford University Medical Center during development of this guideline but at the time of publication will also be employed by Gilead Sciences. Gilead Sciences had no financial or other interest in this project, had no input in the design, content, data collection, or analysis, and had no role in the writing or approval of this article.

American College of Rheumatology/EULAR Remission Criteria for Rheumatoid Arthritis: 2022 Revision

Paul Studenic,[1] Daniel Aletaha,[2] Maarten de Wit,[3] Tanja A. Stamm,[4] Farideh Alasti,[2] Diane Lacaille,[5] Josef S. Smolen,[2] and David T. Felson[6]

This criteria set has been approved by the American College of Rheumatology (ACR) Board of Directors and the EULAR Executive Committee. This signifies that the criteria set has been quantitatively validated using patient data, and it has undergone validation based on an independent data set. All ACR/EULAR-approved criteria sets are expected to undergo intermittent updates.

The ACR is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. In 2011, the American College of Rheumatology (ACR) and EULAR endorsed provisional criteria for remission in rheumatoid arthritis (RA), both Boolean- and index-based. Based on recent studies indicating that a higher threshold for the patient global assessment (PtGA) may improve agreement between the 2 sets of criteria, our goals were to externally validate a revision of the Boolean remission criteria using a higher PtGA threshold and to validate the provisionally endorsed index-based criteria.

Methods. We used data from 4 randomized trials comparing biologic disease-modifying antirheumatic drugs to methotrexate or placebo. We tested the higher proposed PtGA threshold of 2 cm (Boolean2.0) (range 0–10 cm) compared to the original threshold of 1 cm (Boolean1.0). We analyzed agreement between the Boolean- and index-based criteria (Simplified Disease Activity Index [SDAI] and Clinical Disease Activity Index [CDAI]) for remission and examined how well each remission definition predicted later good physical function (Health Assessment Questionnaire [HAQ] score ≤0.5) and radiographic nonprogression.

Results. Data from 2,048 trial participants, 1,101 with early RA and 947 with established RA, were included. The proportion of patients with disease in remission at 6 months after treatment initiation increased when using Boolean2.0 compared to Boolean1.0, from 14.8% to 20.6% in early RA and 4.2% to 6.0% in established RA. Agreement between Boolean2.0 and the SDAI or CDAI remission criteria was better than for Boolean1.0, particularly in early disease. Boolean2.0, SDAI, and CDAI remission criteria had similar positive likelihood ratios (LRs) to predict radiographic nonprogression and a HAQ score of ≤0.5 (positive LR 3.8–4.3). The omission of PtGA (BooleanX) worsened the prediction of good functional outcomes.

Conclusion. Using the Boolean 2.0 criteria classifies more patients as achieving remission and increases the agreement with index-based remission criteria without jeopardizing predictive value for radiographic or functional outcomes. This revised Boolean definition and the previously provisionally endorsed index-based criteria were endorsed by ACR and EULAR.

INTRODUCTION

Disease activity in rheumatoid arthritis (RA) was initially defined by a number of core set variables, agreed upon by the American College of Rheumatology (ACR) and EULAR in the 1990s (1,2). These variables comprised tender joint count (TJC) and swollen joint count (SJC), patient assessment of global disease activity (PtGA) and of pain, evaluator/physician global assessment (EGA), a measure of function such as the Health Assessment Questionnaire (HAQ), and an acute-phase reactant such as C-reactive protein (CRP) level.

At the time of defining the core set variables, remission was more aspirational than a realistic goal (3). Today, however, remission can be obtained in a sizable portion of patients and is seen as a major therapeutic target (4–6). A clinical definition of remission for RA should reflect no or only minimal disease activity, and patients attaining this state should have a low risk of both structural progression and functional impairment (6).

ACR and EULAR endorsed provisional remission criteria over 10 years ago (7). Their publication served the purpose of providing a common definition for this prime treatment target (8). Two types of remission definitions were agreed upon by the ACR/EULAR committee after extensive data analyses and consensus-based deliberations. The Boolean definition required that, to attain remission, each of 4 core set variables (TJC, SJC, PtGA, CRP) must have a value of ≤1. (PtGA is scored on a 0–10-point or 0–10-cm scale, CRP in mg/dl.) The index-based definition used the remission cutoff point of the simplified disease activity index (SDAI) (9). The committee also endorsed remission criteria that did not include CRP level, namely a Boolean definition that comprised SJC, TJC, and PtGA and an index definition based on the remission threshold of the clinical disease activity index (CDAI) (10).

Since their publication, arguments have been made claiming that remission definitions may, on the one hand, be too stringent, with the risk of overtreatment if used as treatment targets, or, on the other hand, too lenient, proposing addition of imaging confirmation of remission. A particular matter of debate was the requirement of achieving a PtGA score of ≤1; the stringent threshold for the PtGA has been criticized, because some patients do not achieve it despite the absence of tender and swollen joints and an elevated CRP level (11). Moreover, the agreement between the Boolean and index definitions was only moderate, primarily due to the PtGA threshold (12). However, the PtGA is the core set measure most sensitive to change in RA trials (1,13–15), best differentiating between patients receiving active treatment and those receiving placebo. Thus, PtGA is an important measure of disease activity. Consequently, the PtGA was included in the ACR core set, composite activity scores, and remission definitions. However, PtGA may also be influenced by other factors related to RA. For example, patients with pain from irreversible joint damage may have elevations in PtGA even if their RA is in clinical remission (16,17).

To circumvent the strictness of the 1.0 rule for PtGA and to increase the agreement with SDAI-defined remission, a higher PtGA threshold has been proposed (18,19). Furthermore, since the index-based criteria can be used instead of Boolean criteria, both criteria should identify the same patients as having disease in remission. However, remission rates based on SDAI are higher than those using the Boolean criteria, because summing several components permits 1 component, such as the PtGA, to be slightly elevated if compensated by a lower score in others (20). A study evaluating alternative Boolean definitions of remission, with PtGA thresholds ranging 1.0–2.5, found that using a threshold of 2 cm (Boolean2.0) led to a higher agreement with the index-based definition without jeopardizing the strong association between remission and subsequent good functional and radiographic outcomes, a key criterion in the development of the provisional definition of remission (12). The purpose of the present study is to externally validate the performance characteristics of this revision of the Boolean criteria (12) and provide external validation of the provisionally endorsed SDAI and CDAI remission definitions. This provides the evidence base for ACR and EULAR to fully endorse the remission criteria, changing their status from the current "provisional" to a "definite" status.

PATIENTS AND METHODS

Patients. RA patient data were retrieved from 4 clinical trials testing the efficacy of biologic disease-modifying antirheumatic drugs (bDMARDs) against placebo or placebo with methotrexate (MTX), with an available observation period between 1 and 2 years. The GO-AFTER trial tested golimumab as an active compound, the FUNCTION and LITHE trials tested tocilizumab, and the SERENE trial tested rituximab. GO-AFTER evaluated patients who were insufficient responders to TNF inhibitors (TNFi), LITHE and SERENE included patients with an insufficient response to MTX, and FUNCTION included MTX-naive patients with early RA. Results and detailed patient characteristics of the individual trials have been previously reported (21–24). These trials included RA patients with varying disease durations and treatment

histories. In all 4 trials, the PtGA was evaluated using a 100-mm visual analog scale (VAS).

Definitions of remission and their modifications. The Boolean definition includes SJC, TJC, PtGA (cm), and CRP levels (mg/dl); for a patient to meet remission criteria, all component scores must be ≤1 (in the case of a 100-mm VAS, this translates to a score of ≤10). A version without CRP was also approved by the ACR/EULAR committee (3-variable Boolean [3vBoolean]). The SDAI-based definition of remission sums the scores for the components used in the Boolean definition in addition to EGA, and patients meet criteria if the score is ≤3.3. The CDAI-based remission definition consists of the same components, excluding CRP level, and remission is fulfilled at a score of ≤2.8 (7).

Similar to a previous study (12), we increased the threshold of the PtGA criterion by steps of 0.5 cm from 1 cm up to 2.5 cm, and labeled these as Boolean1.0, Boolean1.5, Boolean2.0, and Boolean2.5. The Boolean definition that does not include the PtGA criterion was labeled as BooleanX; in this definition, only CRP, TJC, and SJC needed a score of ≤1 to attain remission, regardless of PtGA value (25).

Statistical analysis. We performed descriptive analyses and tested the revised Boolean2.0 criteria against the provisional Boolean1.0 criteria for convergent and predictive validity. Finally, we investigated the impact of the exclusion of the PtGA from the definition of remission (BooleanX). Analyses were performed on 6-month and 12-month data using SPSS Statistics 25 and Stata version 15. An experienced patient research partner (MW) was involved throughout the study. He took part in all meetings, reviewed data at different time points, and provided written as well as oral feedback. His contribution focused on a critical review of the PtGA as part of the RA definition of remission.

Descriptive analysis. We analyzed how the rates of remission at 6 and 12 months after treatment initiation in the trials were affected by the different modifications described above. For the Boolean modifications, we also studied which components prevented achievement of full remission by identifying participants who fulfilled 3 of 4 required criteria but not all 4 of them (11).

Convergent validity. We tested the agreement of different Boolean criteria with the index-based remission definitions. We cross-tabulated remission fulfilment for Boolean remission versions with the SDAI and CDAI definitions and analyzed their agreement using McNemar's test for agreement with kappa statistics. In addition, the well-established concordance between SDAI- and CDAI-defined remission was tested to confirm the interchangeability of these definitions.

We examined the optimal PtGA threshold to achieve concordance with SDAI-defined remission by carrying out classification and regression trees (CART) analyses (R rpart package; https://cran.r-project.org/web/packages/rpart/index.html), in which, after assuming that CRP, TJC, and SJC were all in remission (BooleanX), we asked what threshold of PtGA would provide the best prediction of SDAI-defined remission.

Predictive validity. As a next step, we explored the impact of using the modified Boolean- and index-based remission definitions assessed at 6 months after treatment initiation on outcomes at 1 year. Differences in mean radiographic progression (based on the change in modified total Sharp and van der Heijde score [mTSS] between baseline and 1 year) and the proportions of patients without progression (change in score ≤0) and with good function at 1 year (HAQ ≤0.5) were assessed. Attaining an HAQ of ≤0.5 without radiographic progression at 1 year of treatment was defined as a good combined outcome, similar to the procedure used to develop the provisional ACR/EULAR remission definition (7). These analyses were repeated separately for early and late RA participants. Positive and negative likelihood ratios (LRs) were calculated separately for each remission definition to assess predictive validity for good functional and structural outcomes.

Impact of PtGA score and PtGA exclusion from the remission definition. In addition to the comparison of Boolean2.0 to Boolean 1.0, we analyzed the effect of excluding PtGA from remission criteria (BooleanX) in the context of each of the above analyses.

RESULTS

Patients, remission rates, and components limiting achievement of remission. Data from 2,048 clinical trial participants, 1,101 with early RA (mean ± SD disease duration 0.8 ± 0.5 years) and 947 with established RA (mean ± SD disease duration 7.1 ± 5.4 years), were included. As expected, using Boolean2.0 yielded higher remission rates compared to Boolean1.0 at 6 months: 20.6% (n = 227) compared to 14.8% (n = 163) in early RA; 6.0% (n = 57) versus 4.2% (n = 40) in established RA (Figure 1). These correspond to a relative increase in remission rates of 39% and 42%, in early and established RA, respectively. This trend was consistent at 1 year, although remission rates were generally higher (Supplementary Figure 1, on the *Arthritis & Rheumatology* website at https://onlinelibrary.wiley.com/doi/10.1002/art.42347). Omitting the PtGA criterion using the BooleanX definition further increased remission rates over Boolean2.0, in early RA (from 227 patients [20.6%] to 297 patients [27%]) and in established RA (from 57 patients [6%] to 95 patients [10%] patients at 6 months), with relative increases of 31% and 66%, respectively.

Within the total study population, 311 participants (15.2%) achieved "near misses" of Boolean remission, meaning that they fulfilled 3 of the 4 criteria. In 60% of these participants, this was due to not meeting the criterion of PtGA ≤1cm. By using Boolean2.0, this proportion was reduced to 47% of all near misses. Consequently, among all participants, 14% were classified as having Boolean2.0-defined remission, 5% missed achieving remission only because of the PtGA criterion, and 3% missed achieving

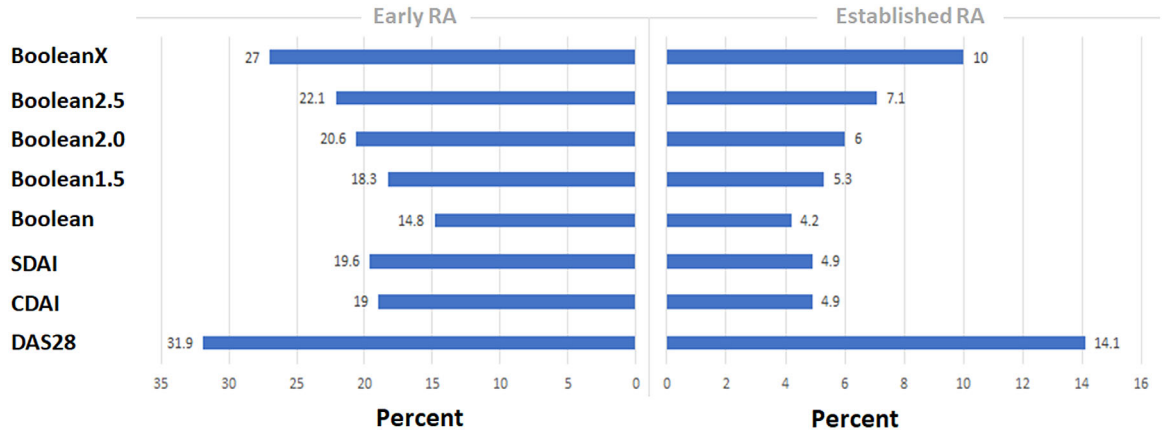

Figure 1. Rates of rheumatoid arthritis (RA) disease remission according to modified Boolean classifications, using a patient global assessment (PtGA) threshold of 1.0 ("Boolean"), 1.5, 2.0, 2.5, or omitting the PtGA completely (BooleanX), as well as according to the Simplified Disease Activity Index (SDAI), Clinical Disease Activity Index (CDAI), and Disease Activity Score in 28 joints (DAS28) definitions. Rates at 6 months after treatment initiation are shown for patients with early RA and those with established RA.

remission only because of the SJC criterion (Supplementary Figure 2, https://onlinelibrary.wiley.com/doi/10.1002/art.42347).

Convergent validity. Increasing the PtGA cutoff from 1.0 to 2.0 cm for participants with early RA yielded higher concordance rates between Boolean- and SDAI-defined criteria for remission. This led to more participants contemporaneously fulfilling the SDAI and respective Boolean remission definition (increase from 71% to 92% of participants when using Boolean1.0 versus Boolean2.0) (Table 1). Rates of concordantly classified participants with respect to remission increased from 93.4% to 95.9% at 6 months. A similar increase in concordantly classified participants was observed for the agreement between the corresponding Boolean and CDAI definitions (Supplementary Table 1, https://onlinelibrary.wiley.com/doi/10.1002/art.42347). In patients with established RA, the percentage classified as having disease in remission by Boolean and CDAI or SDAI definitions likewise increased from 74% to 94% for SDAI and from 70% to 83% for CDAI, when using Boolean1.0 versus Boolean 2.0; and from 78% to 96% when using 3vBoolean1.0 versus 3vBoolean2.0 to assess agreement with CDAI. The proportion of participants concordantly classified as having disease in remission remained similar in established RA.

Kappa analyses showed higher agreement between SDAI-defined remission and Boolean2.0-defined than with Boolean1.0-defined remission at 6 months (Figure 2). The 12-month data showed similar results and are depicted in Supplementary Figure 3 (https://onlinelibrary.wiley.com/doi/10.1002/art.42347). Kappa estimates and 95% confidence intervals (95% CIs) of agreement with SDAI- and CDAI-defined remission at 6 months increased when using Boolean2.0 compared to Boolean1.0 definitions (0.86 [95% CI 0.83–0.89] versus 0.77 [95% CI 0.74–0.82] for SDAI at 6 months, and 0.81 [95% CI 0.77–0.84] versus 0.76 [95% CI 0.72–0.81] for CDAI at 6 months) (kappa

Kappa estimates and 95% CIs are provided in the accompanying table. See Figure 1 for definitions.

curves for CDAI are shown in Supplementary Figure 4, https://onlinelibrary.wiley.com/doi/10.1002/art.42347).

A further increase in the PtGA threshold beyond 2 cm led to a decrease in concordance. Reduced concordance was particularly seen when omitting the PtGA (BooleanX) both in terms of percentage agreement and according to kappa estimates (Table 1 and Figure 2).

Additionally, CART analyses confirmed the percent agreement and kappa results: in participants with SJC, TJC, and CRP values of ≤1, and PtGA values of ≤2.3 cm at 6 months and ≤1.8 cm at 12 months showed the highest likelihood of concurrent SDAI-defined remission. The same analyses stratified by early or established RA yielded a PtGA threshold value of ≤2.3 cm in early RA and ≤1.4 cm in established RA at 6 months (≤1.5 cm in early RA and ≤1.9 cm in established RA at 12 months). Generally, all agreement estimates point to 2.0 cm as the optimal threshold.

Predictive validity. We studied rates of participants achieving a good functional outcome (HAQ ≤0.5) and no radiographic progression (ΔmTSS) at 1 year for participants classified by the different Boolean definitions at 6 months.

Similar results were found for Boolean2.0 and index-based definitions when predicting good functional outcome. HAQ scores at 12 months were as follows: mean ± SD 0.24 ± 0.40 for Boolean1.0, 0.31 ± 0.45 for Boolean2.0, 0.41 ± 0.53 for BooleanX, 0.27 ± 0.42 for SDAI, and 0.26 ± 0.42 for CDAI. Fewer participants scored an HAQ of ≤0.5 when the PtGA was omitted (70% in BooleanX versus 78% in Boolean2.0) (Table 2). Increasing the PtGA threshold for Boolean-based remission was associated with a linear increase in HAQ scores. While there was a drop in positive LR from 6.1 to 4.4 when using the Boolean2.0, this was similar to the positive LR predicting a good functional outcome for SDAI- and CDAI-based remission, which ranged from 4.3 to 4.9.

Table 2 outlines the similarity of LRs for predicting lack of radiographic progression during the first year when the different remission definitions were fulfilled at 6 months of treatment. The radiographic outcomes were similar regardless of the PtGA threshold or whether PtGA was included in the Boolean criteria, and scores were similar between different definitions (mean ± SD ΔmTSS 0.29 ± 2.08 for Boolean1.0, 0.25 ± 1.81 for Boolean2.0, 0.21 ± 1.9 for BooleanX, 0.27 ± 1.86 for SDAI, and 0.27 ± 1.9 for CDAI). This observation is consistent with previous findings that PtGA is not associated with radiographic

progression (12,26). Using the different Boolean definitions as well as index-based definitions led to similar proportions of participants with disease in remission who had radiographic progression (defined as ΔmTSS>0) during the first year (29.6% for Boolean1.0, 28.5% for Boolean2.0, 28.6% for BooleanX, 28.2% for SDAI, and 28.6% for CDAI).

The proportion of participants achieving both good radiographic and functional outcomes were similar for all remission definitions, from 57% to 60% (58.6% for Boolean1.0, 57.3% for Boolean 2.0, 59.2% for SDAI, and 60.4% for CDAI), except for BooleanX (50.8%). Again, index-based remission definitions performed similarly to Boolean1.0 and Boolean2.0 definitions with respect to their predictive ability (positive LR between 3.8 and 4.3). This pattern could also be seen when analyzing data on early RA and established RA, separately (Table 2). However, good functional outcomes when using BooleanX were even less frequent in established RA compared to early RA (HAQ ≤0.5 in established RA was 57% compared to 74% in early RA). Of note, no differences in radiographic progression in patients with established RA were observed between the remission definitions fulfilled. Overall, more than two-thirds of patients with established RA showed radiographic progression throughout the first year.

DISCUSSION

This study provides evidence of external validation of the previously proposed modification of the Boolean ACR/EULAR remission criteria, to include a threshold of 2 cm rather than 1 cm for the PtGA criterion, and of the provisionally endorsed index-based remission definitions. The study was performed using independent clinical trial data sets not included in any of the previous studies (e.g., the data sets generating the provisional definition of remission and the recent analyses on raising the PtGA threshold [7,12] in which the revised threshold was derived). Our study assessed different aspects of validity for the revised definition of remission. The composition of this patient population was heterogenous in terms of disease duration and previous DMARD treatments, and our results are therefore applicable to a broad spectrum of patients with RA (21–24).

The remission validation outlined here builds on work done 10 years ago when the selection of components was undertaken by a large ACR/EULAR consortium (7). Due to criticism around the stringently low threshold of the PtGA component within the Boolean remission definition (11,25,27) and concerns that the 2 approaches (Boolean-based versus index-based) to remission were not concordant, alternative thresholds for the PtGA were explored using multiple clinical trial data sets (12). Our analyses support the notion of a slight increase of the PtGA threshold since it provides better agreement with the SDAI remission definition and higher rates of Boolean-defined remission, without jeopardizing the prediction of good long-term functional and radiographic outcomes.

Our results replicate previous findings that a Boolean definition using 2 cm as threshold for PtGA (Boolean2.0) yields better agreement with both index-based remission definitions than Boolean1.0 (12). Furthermore, patients who attain Boolean2.0, CDAI, and SDAI remission thresholds at 6 months have a higher likelihood of good functional and radiographic outcomes after 12 months of treatment than those attaining Boolean-based disease remission without PtGA (BooleanX). We have also shown the agreement between the 3-variable Boolean approach definition and the CDAI definition, which can be applied during a clinic visit, without knowledge of current acute-phase reactant levels.

The PtGA threshold within the remission criteria does not influence the prediction of radiographic nonprogression, as all tested definitions yielded the same positive LRs for nonprogression of ~1.7 and the same proportions of patients not progressing (~79%). This is consistent with findings from a recent meta-analyses including data from 11 clinical trials showing that people fulfilling the SJC, TJC, and CRP criteria but not the PtGA criterion demonstrate better radiographic outcomes than those not in any Boolean remission category (26). We note that successful management of RA is not only defined by the prevention of joint damage, but, ideally, attaining remission should also prevent residual symptoms that matter to patients, such as pain, fatigue, and anxiety.

The PtGA has not only been criticized for its stringent threshold in the remission definition. The Outcome Measures in Rheumatology (OMERACT) Working Group focusing on "Remission in RA: Patient Perspective" questioned whether the PtGA is the best instrument to reflect the perspective of patients in the current Boolean remission definition. They explored the effect of replacing PtGA with 3 patient-assessed domains identified by patients as most important: pain, fatigue, and independence. Their search for a better incorporation of the patient perspective has not yet resulted in a promising set of validated patient-reported outcome measures that can replace the PtGA. In their most recent working group report, they concluded that there is currently insufficient evidence to propose a change to the existing ACR/EULAR remission criteria (28). This report also discussed the concept of a "dual-target" approach, trying to decouple the assessment of disease activity from disease impact in defining remission (25,29). At this stage no data are available about the effectiveness and feasibility of such a dual-target approach.

Concerns have been expressed that the ACR/EULAR remission criteria allow few patients to achieve disease remission. Within our validation work, we additionally provide data on the shift in remission frequencies and the distribution of patients that miss Boolean-defined remission due to fulfilling only 3 of 4 criteria. By using a threshold of 2 cm rather than 1 cm in the revised Boolean definition, 40% more participants in our data sets achieved disease remission (14% instead of 10%). Importantly, when applying the Boolean2.0 definition, the SJC criterion threshold of 1 seems to be nearly as prominent in limiting participants

23265205, 0, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/art.42347, Wiley Online Library on [24/10/2022]. attaining full remission as the PtGA criterion (3% due to high SJC and 5% to high PtGA when fulfilling the other 3 criteria). The revised PtGA threshold of 2 cm has been proposed as 1 item in a set of 7 criteria that defined minimal disease activity of RA by OMERACT in 2005 (30). Notably, the definition of remission should remain strict and ensure beneficial long-term outcomes for patients with RA and prevent unnecessary treatment escalation at the same time. Furthermore, it appears that changes in the overall approach to treating RA before patients enter clinical trials or trends over time have led to much higher provisional ACR/EULAR remission rates in more recent clinical trials than in earlier ones, with recent rates reaching ~30% in early disease, 20% in patients with insufficient response to MTX, and 15–20% in patients with insufficient response to bDMARDs (31–35).

A preferable approach for more patients to achieve remission is to foster a collaborative relationship between patients and clinicians, to initiate treatment early, and to utilize a treat-to-target approach (8), rather than omitting potentially problematic items such as the PtGA (36,37). Studies have shown that a treat-to-target approach is not yet fully implemented in clinical practice; in one-third of instances where treatment was not increased, this was influenced by factors unrelated to RA and in another third it was the patient's preference to continue receiving the current treatment (38,39). All measurements and their interpretations need, in any case, to be complemented by the discussion between the patient and rheumatology clinician to reflect and decide on the appropriate steps in a shared decision (40,41).

Remission has become a key target for the management of patients with RA (42). The ACR/EULAR 2011 initiative on remission criteria was undertaken to harmonize the definition of the term "remission" and thus to facilitate the fair assessment and comparison of remission rates in clinical trials and clinical practice (e.g., for different health care settings or providers). It will be helpful to further study the performance of the revised criteria in trials using other antirheumatic drugs, such as JAK inhibitors, and in other countries and ethnic groups, since RA severity and the interpretation of the PtGA may vary across ethnicities. We validated the results of the performance of the Boolean2.0 and the provisionally endorsed index-based remission definitions. With the validation of the threshold of 2 cm for the PtGA, we propose that these revised ACR/EULAR remission criteria be adopted both for future clinical trials and as a target in clinical practice.

2022 American College of Rheumatology (ACR) Guideline for Exercise, Rehabilitation, Diet, and Additional Integrative Interventions for Rheumatoid Arthritis

Guideline Summary

Revised January 13, 2023

This American College of Rheumatology (ACR) guideline addresses the use of exercise, rehabilitation, diet, and additional integrative interventions in conjunction with disease-modifying anti-rheumatic drugs (DMARDs) as part of an integrative management approach for people with rheumatoid arthritis (RA).

An interprofessional guideline development group developed clinically relevant Population, Intervention, Comparator, and Outcome (PICO) questions. A literature review team then completed a systematic literature review and applied the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach to rate the certainty of evidence. An interprofessional Voting Panel (n=20 participants) that included three persons with RA achieved consensus on the direction and strength of recommendations. These teams included individuals with expertise in epidemiology, exercise physiology, GRADE methodology, integrative medicine, nursing, nutrition, occupational therapy, physical therapy, rheumatology, and social work. Guiding principles through the guideline development process specified that integrative interventions considered in this guideline should complement pharmacologic treatments, highlighted an interprofessional approach for the management of RA, and emphasized that shared decision-making is needed when caring for people with RA.

The Voting Panel achieved consensus on one strong recommendation for exercise and conditional recommendations pertaining to exercise type, rehabilitation interventions, diet interventions, and additional integrative interventions (**Table 1**). **These recommendations are specific to RA management,** understanding that other medical indications and general health benefits may exist for many of these interventions.

This guideline provides initial ACR recommendations on integrative interventions for the management of RA to accompany DMARD treatments. The broad range of interventions included in these recommendations illustrates the importance of an interprofessional team-based approach to RA management. The conditional nature of most recommendations requires clinicians to engage patients in shared decision-making when applying these recommendations.

Table 1. Recommendations on integrative interventions for the management of rheumatoid arthritis (RA)

Exercise	Rehabilitation	Diet	Additional
Consistent engagement in exercise (++)	Comprehensive occupational therapy (+)	Mediterranean-style diet (+)	Standardized self-management program (+)
Aerobic exercise (+)	Comprehensive physical therapy (+)	Against formally defined diet other than Mediterranean-style (-)	Cognitive behavioral therapy and/or mind-body approaches (+)
Aquatic exercise (+)	Hand therapy exercises (+)	Against dietary supplements (-)	Acupuncture (+)
Resistance exercise (+)	Splinting, orthoses, compression, bracing, and/or taping (+)		Massage therapy (+)
Mind-body exercise (+)	Joint protection techniques (+)		Thermal modalities (+)
	Activity pacing, activity modification, energy conservation, and/or fatigue management (+)		Against electrotherapy (-)
	Assistive devices, adaptive equipment, and/or environmental adaptations (+)		Against chiropractic therapy (-)
	Vocational rehabilitation, work site evaluations and/or modifications (+)		

Strong recommendations **for** an intervention are shown in dark green and ++.
Conditional recommendations **for** an intervention are shown in light green and +.
Conditional recommendations **against** an intervention are shown in light red and -.

This summary was approved by the ACR Board of Directors on October 31, 2022. These recommendations are included in a full manuscript, which will be submitted for publication in Arthritis & Rheumatology and Arthritis Care and Research.

INTRODUCTION

Rheumatoid arthritis (RA) is a symmetric, inflammatory, peripheral polyarthritis of unknown etiology. It typically leads to deformity through the stretching of tendons and ligaments and destruction of joints through the erosion of cartilage and bone. If it is untreated or unresponsive to therapy, inflammation and joint destruction lead to loss of physical function, inability to carry out daily tasks of living, and difficulties in maintaining employment. Uncontrolled inflammation may have other health risks including higher rates of cardiovascular disease, osteoporosis, and certain types of cancer (eg, lymphoma).

Early recognition and treatment with disease-modifying antirheumatic drugs (DMARDs) is important in achieving control of disease and prevention of joint injury and disability. However, in patients with early disease, the joint manifestations are often difficult to distinguish from other forms of inflammatory polyarthritis. The more distinctive signs of RA, such as joint erosions, rheumatoid nodules, and other extraarticular manifestations, are seen primarily in patients with longstanding, poorly controlled disease but are frequently absent on initial presentation.

This topic will review the approach to the diagnosis and differential diagnosis of RA. The clinical features of this disorder, its extraarticular manifestations, and laboratory markers that are clinically useful in the diagnosis of RA are discussed in detail separately. (See "Clinical manifestations of rheumatoid arthritis" and "Overview of the systemic and nonarticular manifestations of rheumatoid arthritis" and "Biologic markers in the diagnosis and assessment of rheumatoid arthritis".)

EVALUATION FOR SUSPECTED RA

Rheumatoid arthritis (RA) should be suspected in the adult patient who presents with inflammatory polyarthritis. The initial evaluation of such patients requires a careful history and physical examination, along with selected laboratory testing to identify features that are characteristic of RA or that suggest an alternative diagnosis. (See "Clinical manifestations of rheumatoid arthritis" and 'Differential diagnosis' below.)

We focus especially on the following for the purposes of diagnosis:

- We perform a thorough medical history, with particular attention to joint pain, reported swelling, and the presence, location (peripheral joints rather than low back), and duration (at least 30 minutes) of morning stiffness. The absence of other conditions or symptoms suggesting an alternative diagnosis, such as psoriasis, inflammatory bowel disease (IBD), or a systemic rheumatic disease such as systemic lupus erythematosus (SLE), helps to exclude other disorders.

  Symptoms of arthritis that have been present for a short time (eg, less than six weeks) may well be due to an acute viral polyarthritis rather than to RA. The longer symptoms persist, the more likely the diagnosis of RA becomes. Thus, in patients presenting very early, close observation with frequent follow-up appointments is required, with repeated evaluations for joint swelling and elevations in acute phase reactants, before establishing a formal diagnosis.

  In a minority of patients, several such visits are required before the diagnosis of RA is established. (See "Clinical manifestations of rheumatoid arthritis", section on 'Typical 'classic' RA' and 'Differential diagnosis' below.)

- A complete physical examination is indicated to assess for synovitis, including the presence and distribution of swollen or tender joints and limited joint motion; extraarticular disease manifestations, such as rheumatoid nodules; and signs of diseases, such as SLE or psoriasis, included in the differential diagnosis. (See "Clinical manifestations of rheumatoid arthritis", section on 'Symptoms and physical findings' and "Rheumatoid nodules" and 'Differential diagnosis' below.)

- We perform the following laboratory tests, which support the diagnosis if positive and/or elevated:

  - Rheumatoid factor (RF) and anti-citrullinated peptide antibodies (ACPA) – We perform both RF and ACPA testing when initially evaluating a patient with suspected RA. The results of both tests are informative, since a positive result for either test increases overall diagnostic sensitivity, while the specificity is increased

when both tests are positive. Despite this, both tests are negative on presentation in up to 50 percent of patients and remain negative during follow-up in 20 percent of patients with RA.

For most patients, serologic evidence of disease will be present by the time symptoms are noted. However, where the diagnosis is uncertain, repeating a serologic analysis for ACPAs and RF 6 to 12 months after the initial evaluation can identify individuals who develop serologic evidence to support the diagnosis. Once the diagnosis of RA is established, evidence does not support serial testing of these serologies for disease prognosis [1]. (See "Biologic markers in the diagnosis and assessment of rheumatoid arthritis", section on 'Rheumatoid factors' and "Biologic markers in the diagnosis and assessment of rheumatoid arthritis", section on 'Anti-citrullinated peptide antibodies'.)

- Erythrocyte sedimentation rate (ESR) and serum C-reactive protein (CRP) – Both the ESR and CRP are typically elevated in RA. These may also be repeated subsequent to the initial evaluation and diagnosis for assessment and monitoring of systemic inflammation, as indicated, over the course of disease. (See "Biologic markers in the diagnosis and assessment of rheumatoid arthritis", section on 'Erythrocyte sedimentation rate' and "Biologic markers in the diagnosis and assessment of rheumatoid arthritis", section on 'C-reactive protein'.)

- We perform the following testing in all patients, which may be helpful in the differential diagnosis of RA and as baseline testing for monitoring of disease activity or progression and medication safety:

  - Antinuclear antibody (ANA) testing – A negative ANA helps exclude SLE and other systemic rheumatic diseases; the ANA may be positive in up to one-third of patients with RA. In patients with a positive ANA, anti-double stranded deoxyribonucleic acid (DNA) and anti-Smith antibody testing should also be performed; these antibodies have higher specificity for SLE. (See "Measurement and clinical significance of antinuclear antibodies".)

  - Complete blood count (CBC) with differential and platelet count, tests of liver and kidney function, serum uric acid, and a urinalysis – The CBC is often abnormal in RA, with anemia and thrombocytosis consistent with chronic inflammation. Liver and kidney testing abnormalities could indicate a disorder other than RA; if caused by comorbid conditions, they may affect therapeutic choices or drug dosing. Hyperuricemia may prompt additional efforts, including arthrocentesis and crystal search, to exclude gout; polyarticular gout can infrequently be mistaken for RA. (See 'Differential diagnosis' below and "Hematologic complications of rheumatoid

arthritis", section on 'Anemia' and "Hematologic complications of rheumatoid arthritis", section on 'High or low platelet count'.)

- Radiographs of the hands, wrists, and feet – We obtain radiographs during the initial evaluation primarily as a baseline for monitoring disease progression. However, characteristic joint erosions may be observed in patients presenting with symptoms for the first time and, hence, aid in diagnosis and prognosis. Additionally, in patients with other disorders, such as psoriatic arthritis, spondyloarthropathy, gout, or chondrocalcinosis, radiographic changes more characteristic of these conditions may point to an alternative diagnosis. (See '2010 ACR/EULAR criteria' below and 'Differential diagnosis' below and "Clinical manifestations of rheumatoid arthritis", section on 'Imaging'.)

- We perform the following studies in selected patients:

  - Serologic studies for infection – In patients with a very short duration of symptoms (less than six weeks) particularly those who are seronegative for ACPA and RF, we perform serologic testing for human parvovirus B19, hepatitis B virus (HBV), and hepatitis C virus (HCV). In areas endemic for Lyme disease, we perform serologic studies for Borrelia as well. In people who live in or have traveled to parts of the world where mosquito (*Aedes aegypti* and *Aedes albopictus)*-bite transmitted viral diseases are prevalent, chikungunya virus infection should be suspected in patients with fever and arthralgia, as this may be followed by a chronic polyarthritis; diagnosis is confirmed by serologic tests. Other mosquito-borne illnesses such as Zika or dengue may be considered in the appropriate clinical context. (See 'Viral polyarthritis' below and "Viruses that cause arthritis" and "Diagnosis of Lyme disease" and "Chikungunya fever: Epidemiology, clinical manifestations, and diagnosis".)

  - Synovial fluid analysis – We perform arthrocentesis and synovial fluid analysis for the diagnosis or exclusion of gout, pseudogout, or an infectious arthritis if a joint effusion is present and if there is uncertainty regarding the diagnosis, particularly in the setting a monoarthritis, oligoarthritis, or asymmetric joint inflammation. Synovial fluid testing should include a cell count and differential, crystal search, and Gram stain and culture. (See "Clinical manifestations of rheumatoid arthritis", section on 'Laboratory findings' and "Synovial fluid analysis".)

  - Magnetic resonance imaging (MRI) and ultrasound – MRI studies and ultrasonography do not have an established role in the routine evaluation of patients with polyarthritis. However, MRI and ultrasound are more sensitive than radiography at detecting changes resulting from synovitis and may be helpful in establishing the presence of synovitis in patients with normal radiographs and

uncertainty regarding either the diagnosis or the presence of inflammatory changes, such as patients with obesity or subtle findings on examination. Abnormalities such as synovitis, osteitis, and erosion observed on imaging studies should be considered consistent with, but not diagnostic of, RA as each can be observed in other conditions. (See "Clinical manifestations of rheumatoid arthritis", section on 'Imaging'.)

DIAGNOSIS

Our diagnostic criteria — The diagnosis of rheumatoid arthritis (RA) can be made when the following clinical features are all present:

- Inflammatory arthritis involving three or more joints. (See "Clinical manifestations of rheumatoid arthritis", section on 'Symptoms and physical findings'.)
- Positive rheumatoid factor (RF) and/or anti-citrullinated peptide/protein antibody (ACPA), such as anti-cyclic citrullinated peptide antibody (anti-CCP) testing. (See "Biologic markers in the diagnosis and assessment of rheumatoid arthritis", section on 'Anti-citrullinated peptide antibodies'.)
- Elevated levels of C-reactive protein (CRP) or the erythrocyte sedimentation rate (ESR). (See "Biologic markers in the diagnosis and assessment of rheumatoid arthritis", section on 'Erythrocyte sedimentation rate'.)
- Diseases with similar clinical features have been excluded, particularly psoriatic arthritis, acute viral polyarthritis, polyarticular gout or calcium pyrophosphate deposition disease, and systemic lupus erythematosus (SLE). (See 'Differential diagnosis' below.)
- The duration of symptoms is more than six weeks.

These criteria are consistent with the 2010 American College of Rheumatology (ACR)/European Alliance of Associations for Rheumatology (EULAR; formerly known as European League Against Rheumatism) classification criteria for RA (see '2010 ACR/EULAR criteria' below). A higher titer of RF or ACPA and a greater number of swollen joints each increases the probability of RA.

The diagnosis of RA may also be made in some patients who do not meet all of our criteria (eg, patients negative for RF and ACPA). (See 'Patients not meeting above criteria' below.)

Inflammatory arthritis — Arthritis is typically present in the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints of the hands. The wrists are also commonly

involved, as are the second to fifth metatarsophalangeal (MTP) joints in the feet, but any upper or lower extremity joint may be affected. Symmetric polyarthritis, particularly of the MCP, MTP, and/or PIP joints, strongly suggests RA. Although distal interphalangeal (DIP) joint disease can occur in patients with RA, DIP involvement strongly suggests a diagnosis of osteoarthritis or psoriatic arthritis. (See "Clinical manifestations of rheumatoid arthritis", section on 'Symptoms and physical findings' and 'Osteoarthritis' below and 'Psoriatic arthritis' below.)

Serology — RFs occur in 70 to 80 percent of patients with RA. Their diagnostic utility is limited by their relatively poor specificity, since they are found in 5 to 10 percent of healthy individuals, 20 to 30 percent of people with SLE, virtually all patients with mixed cryoglobulinemia (usually caused by hepatitis C virus [HCV] infections), and in those with many other inflammatory conditions. The prevalence of RF positivity in healthy individuals rises with age. Higher titers of RF (at least three times the upper limit of normal) have somewhat greater specificity for RA. Low titer RF levels are thus commonly observed and should be interpreted with caution if the clinical context is not otherwise consistent with RA. (See "Rheumatoid factor: Biology and utility of measurement" and "Biologic markers in the diagnosis and assessment of rheumatoid arthritis", section on 'Rheumatoid factors'.)

Antibodies to citrullinated peptides/proteins are usually measured by enzyme-linked immunosorbent assays (ELISAs) using citrullinated proteins as antigen. ACPAs have a similar sensitivity to RF for RA but have a higher specificity (95 to 98 percent) [2-5]. The specificity is greater in patients with higher titers of ACPAs (at least three times the upper limit of normal). Another test, anti-mutated citrullinated vimentin, gives similar results to ACPA and is used as an alternative in some laboratories [6]. (See "Biologic markers in the diagnosis and assessment of rheumatoid arthritis", section on 'Anti-citrullinated peptide antibodies'.)

Acute phase reactants — Elevations of the ESR and/or CRP level are consistent with the presence of an inflammatory state, such as RA. Normal acute phase reactants may occur in untreated patients with RA, but such findings are infrequent and should prompt consideration of alternative diagnoses [7]. The degree of elevation of these acute phase reactants varies with the severity of inflammation and synovitis. As an example, an ESR of 50 to 80 is not uncommon in patients with severely active RA. By comparison, an ESR of 20 to 30 can be observed with only a few mildly to moderately active joints. Although increased levels of acute phase reactants are not specific for RA, they are often useful for distinguishing inflammatory conditions from noninflammatory disorders that present with musculoskeletal symptoms (eg, osteoarthritis or fibromyalgia). (See "Acute phase reactants" and "Biologic markers in the diagnosis and assessment of rheumatoid arthritis", section on 'Erythrocyte sedimentation rate' and "Biologic markers in the diagnosis and assessment of rheumatoid arthritis", section on 'C-reactive protein'.)

Patients not meeting above criteria — The diagnosis of RA may also be made in patients without all the criteria described in the previous section. Examples include the following:

- **Seronegative RA** – Patients who lack both RF and ACPAs may be diagnosed with RA based upon findings otherwise characteristic of RA if appropriate exclusions have been met. The presence of a large number of swollen joints in a symmetric, small joint pattern or the presence of features such as erosion or rheumatoid nodules provides greater confidence in a diagnosis of RA in the absence of positive serologic testing. Such patients with seronegative RA differ from ACPA-positive patients genetically and in their environmental risks, disease severity, and clinical responsiveness to some medications [8]. Additional research is needed to better characterize this population. (See "Biologic markers in the diagnosis and assessment of rheumatoid arthritis".)

- **Recent onset RA** – To avoid delays in initiation of treatment for patients with a severe disease presentation, patients with disease for less than six weeks may be diagnosed with RA based upon findings otherwise characteristic of RA, including ACPAs, if testing for viral serologies is negative, and if other appropriate exclusions have been met. (See 'Evaluation for suspected RA' above and 'Viral polyarthritis' below.)

- **Inactive RA** – Patients without active arthritis or elevated acute phase reactants (eg, due to treatment of recent onset disease or with longstanding disease) may be diagnosed with RA based upon well-documented past findings characteristic of RA, especially in the presence of positive testing for RF and ACPA, or typical bone erosions on radiography, and in the absence of an alternative more likely diagnosis.

Patients in the several categories above, and other patients who should be diagnosed with RA but do not meet our standard criteria, will generally have findings that are consistent with the 2010 ACR/EULAR classification criteria for RA [9,10]. These criteria were developed for the classification of patients with RA for the purpose of epidemiologic studies and clinical trials, not primarily for clinical diagnosis. Nevertheless, the same features that are of value in classification tend to be useful for the purpose of diagnosis in clinical practice. Further study is required to establish their utility as diagnostic criteria in general practice. (See 'Classification criteria' below.)

CLASSIFICATION CRITERIA

The 2010 American College of Rheumatology (ACR)/European Alliance of Associations for Rheumatology (EULAR) classification criteria focus on features that would identify patients at an earlier stage of disease than would the previously used criteria that had been last revised in 1987 [9-12]. The 1987 ACR criteria were formulated to distinguish patients with

established rheumatoid arthritis (RA) from patients with other defined rheumatic diseases; the 2010 ACR/EULAR criteria for RA focused on identifying the factors, among patients newly presenting with undifferentiated inflammatory synovitis, which could allow for the identification of patients for whom the risk of symptom persistence or structural damage is sufficient to be considered for intervention with disease-modifying antirheumatic drugs (DMARDs) [9,10]. (See '2010 ACR/EULAR criteria' below and '1987 ACR criteria' below.)

2010 ACR/EULAR criteria — Using the 2010 ACR/EULAR classification criteria for RA, classification as definite RA is based upon the presence of synovitis in at least one joint, the absence of an alternative diagnosis that better explains the synovitis, and the achievement of a total score of at least 6 (of a possible 10) from the individual scores in four domains [9,10,13]. The highest score achieved in a given domain is used for this calculation. These domains and their values are:

- Number and site of involved joints
  - 2 to 10 large joints (from among shoulders, elbows, hips, knees, and ankles) = 1 point
  - 1 to 3 small joints (from among the metacarpophalangeal joints, proximal interphalangeal joints, second through fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists) = 2 points
  - 4 to 10 small joints = 3 points
  - Greater than 10 joints (including at least 1 small joint) = 5 points
- Serological abnormality (rheumatoid factor or anti-citrullinated peptide/protein antibody)
  - Low positive (above the upper limit of normal [ULN]) = 2 points
  - High positive (greater than three times the ULN) = 3 points
- Elevated acute phase response (erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP]) above the ULN = 1 point
- Symptom duration at least six weeks = 1 point

In addition to those with the criteria above, which are best suited to patients with newly presenting disease, the following patients are classified as having RA:

- Patients with erosive disease typical of RA with a history compatible with prior fulfillment of the criteria above

- Patients with longstanding disease, including those whose disease is inactive (with or without treatment) who have previously fulfilled the criteria above based upon retrospectively available data

1987 ACR criteria — It is important to recognize that RA was defined in virtually all clinical trials of drugs for RA initiated from 1987 through 2010 based upon the criteria developed and validated by the ACR (previously the American Rheumatism Association) in 1987 (table 1) [11,12]. A patient was classified as having RA if at least four of these seven criteria were satisfied; four of the criteria must have been present for at least six weeks: morning stiffness, arthritis of three or more joint areas, arthritis of the hands, and symmetric arthritis. Rheumatoid factor (RF) was included as a criterion, but anti-citrullinated peptide antibody (ACPA) testing was not available at that time. The other two criteria were rheumatoid nodules and radiographic erosive changes typical of RA, but these are generally not present in the early stages of disease.

Thus, while these criteria were very good at separating inflammatory from noninflammatory arthritis, the major drawback of the 1987 criteria has been their insensitivity in identifying some patients with early disease who subsequently develop typical established RA [12]. The criteria also did not require any exclusions, and patients could initially fulfill the diagnostic criteria but occasionally evolve into other diagnoses, particularly systemic lupus erythematosus (SLE), Sjögren's syndrome, scleroderma, mixed connective tissue disease, psoriatic arthritis, and crystalline arthritis.

DIFFERENTIAL DIAGNOSIS

Joint pain involving the hands is a common clinical presentation for a variety of conditions, thus a number of other diagnoses must be considered in the differential diagnosis of rheumatoid arthritis (RA). The evaluation of patients with polyarticular pain is described in detail separately (see "Evaluation of the adult with polyarticular pain"), and the features of disorders that are included in the differential diagnosis of RA are described below.

Viral polyarthritis — A number of viral infections may cause an acute viral polyarthritis.

- Viral infections such as rubella [14], parvovirus B19 [15], and hepatitis B virus (HBV) can cause an acute polyarthritis syndrome that may be mistaken for the inflammatory polyarthritis of RA. However, the syndrome is usually short-lived, lasting only from a few days to several weeks, and rarely beyond six weeks. Hepatitis C virus (HCV) can cause a polyarthritis or oligoarthritis in a minority of patients, but is more commonly associated with arthralgias.

Serologic testing can help identify patients with HBV, HCV, or human parvovirus B19 in some individuals with early disease, but a viral etiology cannot always be excluded until after symptoms are present for at least six to eight weeks in the absence of diagnostic serologic testing for a specific virus (see "Viruses that cause arthritis") Unlike rheumatoid factor (RF) (which may occur in patients with a variety of infections, including HCV infection), anti-citrullinated peptide antibodies (ACPAs) are usually negative in patients with HCV infection who do not have RA. For mild disease presentations, conservative approaches to management may be reasonable for symptoms lasting less than six weeks. (See "Biologic markers in the diagnosis and assessment of rheumatoid arthritis", section on 'Anti-citrullinated peptide antibodies'.)

- Increasingly reported in travelers, alphaviruses are globally distributed mosquito-borne ribonucleic acid (RNA) viruses that cause epidemics of polyarthritis/arthralgia [16,17]. Among all of the viruses that can cause arthritis, the alphaviruses are unusual because nearly all symptomatic infections in adults result in joint symptoms. The incubation period lasts from several days to three weeks; infection is typically associated with triad of fever, arthritis, and rash [16]. However, all aspects of the triad may not be present, thereby making the diagnosis difficult.

  One such alphavirus, Chikungunya, has become a global disease with increasing world travel and has caused large outbreaks in Italy, India, Indian Ocean islands, and in the Caribbean region and surrounding countries [18,19]. Patients with more persistent disease can mimic seronegative RA clinically to a sufficient degree to satisfy the 2010 classification criteria for RA if the initial symptoms of fever and rash and history of travel to an endemic region are not appreciated [20]. Serologic studies can help to document exposure to the Chikungunya virus. (See "Chikungunya fever: Epidemiology, clinical manifestations, and diagnosis", section on 'Clinical manifestations'.)

  Alphavirus infections generally resolve over three to six months. The diagnosis of alphavirus infection can be made by appropriate serologic testing in travelers from endemic areas with persistent arthritic symptoms. (See "Viruses that cause arthritis", section on 'Alphaviruses' and "Chikungunya fever: Epidemiology, clinical manifestations, and diagnosis".)

- A large joint arthritis has been reported in association with human T lymphotropic virus type 1 (HTLV-I) [21]. These infections are sometimes associated with the presence of RFs (usually in low titer), antinuclear antibodies (ANA), and elevated acute phase reactants. HTLV-I infections can generally be distinguished from RA by the

finding of specific antiviral antibodies and the typically self-limited nature of arthritis associated with HTLV-I. Testing may be considered in endemic areas.

Other systemic rheumatic diseases — Early RA may be difficult to distinguish from the arthritis of systemic lupus erythematosus (SLE), Sjögren's syndrome, dermatomyositis (DM) and antisynthetase syndrome, and overlap syndromes such as mixed connective tissue disease. RF can also often be elevated in other systemic rheumatic diseases, most notably Sjögren's syndrome. In contrast with RA, these disorders are generally characterized by the presence of other systemic features, such as rashes, dry mouth and dry eyes, myositis, or nephritis, and by various autoantibodies not often seen in RA.

While diagnostic uncertainty in early RA is expected, the diagnosis should become clearer with time.

Taken together, the pattern of longstanding disease, morning stiffness, symmetric arthritis, subcutaneous nodules, and the deformities characteristic of RA does not develop in these other disorders. There are several exceptions to this observation:

- Morning stiffness is common in all inflammatory arthritides. Symmetric arthritis is seen in patients with SLE and can be present in other disorders. Infrequently, nodules similar to those seen in RA may occur in patients with SLE, and other nodular lesions may mimic rheumatoid nodules. (See "Rheumatoid nodules", section on 'Differential diagnosis'.)

- An erosive arthritis has been described in some overlap syndromes, particularly those associated with anti-tRNA synthetases and anti-U1 RNP antibodies [22]. (See "Clinical manifestations and diagnosis of mixed connective tissue disease".)

- Jaccoud's arthropathy occurs in up to 5 to 10 percent of patients with Sjögren's syndrome or SLE and can also occur in sarcoidosis [23]. (See "Arthritis and other musculoskeletal manifestations of systemic lupus erythematosus" and "Sarcoid arthropathy".)

  The joint deformities of Jaccoud's arthropathy are not caused by destruction of joints but by loosening and lengthening of periarticular structures and tendons. The ulnar drift or swan neck deformities caused by this disorder resemble RA superficially but can be distinguished by the fact that they are "correctable" on physical examination: fingers with these deformities can be moved manually back into normal alignment. In addition, radiographs in Jaccoud's arthropathy rarely reveal the cartilage loss, erosions, or cysts that are typical of longstanding RA.

Palindromic rheumatism — The term palindromic rheumatism refers to episodes of joint inflammation sequentially affecting one to several joint areas for hours to days, with

symptom-free periods that may last from days to months. Some patients presenting with this syndrome eventually develop a well-defined rheumatic disease, the most common being RA (ranging from 28 to 67 percent); some of the remaining patients develop SLE and other systemic disorders [24,25]. Patients with ACPAs appear more likely to progress to definite RA [26,27]. Close follow-up and specific serologic evaluation can help distinguish among these disorders. (See "Clinical manifestations of rheumatoid arthritis", section on 'Palindromic rheumatism'.)

Osteoarthritis — Osteoarthritis (OA) can be confused with RA in the middle aged or older patient when the small joints of the hands are involved. However, different patterns of clinical involvement usually permit the correct diagnosis (table 2). The following are examples (see "Clinical manifestations and diagnosis of osteoarthritis"):

- OA of the fingers typically affects the distal interphalangeal joints and is frequently associated with Heberden's nodes in this area. In contrast, RA typically affects the MCP and proximal interphalangeal (PIP) joints and is not associated with Heberden's nodes.
- The carpometacarpal joint of the thumb is typically involved in OA.
- Swelling of the joints is hard and bony in OA. In contrast, soft, warm, boggy, and tender joints are typical of RA.
- Stiffness of the joint is a very common feature of RA but is relatively uncommon in OA. Furthermore, the stiffness of RA is characteristically worse after resting the joint (eg, morning stiffness), while the stiffness of OA, if present, is typically worse after any effort and is often described as evening stiffness. Morning stiffness in OA, when present, is usually transient or lasts no more than a few minutes, unlike the more sustained stiffness typical of RA.
- Radiographs also help distinguish RA from OA. OA is characterized by narrowing of the joint space due to cartilage loss and osteophytes due to bone remodeling, but not erosions or cysts.
- OA is classically associated with the absence of RFs and normal levels of acute phase reactants. However, RFs may be present, usually in low titer, consistent with the patient's (older) age.
- Erosive or inflammatory osteoarthritis can cause severe and rapidly progressive arthritis in the small joints of the hands, often at middle age. Swelling in the PIPs with central joint erosion may be present. Central erosions (found in the center of the joint space) should be distinguished from the marginal erosions of RA, which are found at the margin of the joint space. Distinction from RA can be made by characteristic

findings on radiographs as well as a lack of systemic inflammation and serologic markers.

Stenosing tenosynovitis — Tendon pathology in the hand is common among patients with diabetes, thyroid disease, or occupational risk factors, and can resemble the hand pain and tenosynovitis seen in some patients with RA. Narrowing of flexor tendon sheaths may cause triggering, or locking, of the digits and refer pain to the fingers, particularly during activity (see "Trigger finger (stenosing flexor tenosynovitis)"). Hand pain may be present even in the absence of overt triggering. Diabetic cheiroarthropathy is a related condition that results in difficulty in the extension of the digits of the hand. Tendon pathology may be distinguished from RA by eliciting pain over the flexor tendons at the base of the digit and by the absence of synovitis in the joints of the hand. (See "Limited joint mobility in diabetes mellitus".)

Carpal tunnel syndrome — Hand and wrist pain may be a symptom of RA, and synovitis in the wrist from RA may also cause median nerve entrapment and the presence of classic symptoms of carpal tunnel syndrome. Thus, the presence of carpal tunnel syndrome does not exclude concurrent RA. However, carpal tunnel syndrome is common and observed at higher rates in patients with some comorbid conditions (eg, diabetes). A sensation of hand swelling along with burning and numbness, often experienced at night or in the morning, are common symptoms of median nerve entrapment. Carpal tunnel syndrome should be considered in patients who demonstrate a positive Tinel or Phalen sign, have thenar wasting, and/or demonstrate poor hand dexterity or weakness in the "pinch test." (See "Carpal tunnel syndrome: Clinical manifestations and diagnosis".)

Reactive arthritis and arthritis of inflammatory bowel disease — Reactive arthritis often presents as a monoarthritis or oligoarthritis in large joints, such as the knees, and RA may occasionally present in this fashion as well [28]. The physical signs of both reactive arthritis and RA can be identical in the knees. (See "Reactive arthritis".)

The following findings on history, physical examination, or other assessments are more consistent with reactive arthritis than RA:

- History of recent urethritis or enteric infection
- Asymmetric pattern of joint involvement
- Symptoms or signs of enthesopathy (inflammation at the site where a tendon inserts into a bone, eg, the insertion point of the Achilles tendon into the heel)
- Keratoderma blennorrhagica or circinate balanitis (see "Reactive arthritis" and "Reactive arthritis", section on 'Extraarticular signs and symptoms')
- Radiologic evidence of sacroiliitis and/or spondylitis
- The presence of human leukocyte antigen (HLA)-B27

Involvement of the hands in reactive arthritis does not pose as great a diagnostic dilemma as that of the knees. Hand arthritis is more commonly asymmetric than in RA. Furthermore, reactive arthritis will often involve not only the joint but also the tenosynovium, entheses, and surrounding tissues of the digit, giving rise to a characteristic "sausage" swelling of the fingers (or toes if the feet are involved) (picture 1).

The arthritis associated with inflammatory bowel disease (IBD) or other gastrointestinal (GI) disorders is also part of the differential diagnosis. While IBD-related arthritis is more commonly a large-joint oligoarticular arthritis or spondyloarthritis with sacroiliitis, patients with IBD may infrequently develop a peripheral polyarthritis with prominent involvement of the metacarpophalangeal (MCP) joints that can be mistaken for RA. This disorder may be missed if abdominal symptoms or symptoms of diarrhea and/or blood or mucus in the stool are not prominent or are not specifically sought in the history. (See "Clinical manifestations and diagnosis of arthritis associated with inflammatory bowel disease and other gastrointestinal diseases".)

Psoriatic arthritis — Psoriatic arthritis can be difficult to distinguish from RA because a symmetric polyarthritis can be observed in both disorders [29]. We generally make the diagnosis of psoriatic arthritis in such patients who also have psoriasis and are seronegative for RF and ACPA. However, we diagnose RA in those with a symmetric polyarthritis who are seropositive for at least one of these antibodies, since skin psoriasis is so common. However, serologic testing and skin findings may not be informative, since patients with RA may not have RF or ACPA (eg, seronegative RA) and the joint symptoms of psoriatic arthritis may precede the onset of skin disease by many years. Such patients should be evaluated and monitored for other signs more characteristic of psoriatic arthritis, such as nail changes or enthesitis; occasional patients exhibit overlapping features of both disorders. Since management at this stage is highly similar between these disorders, distinguishing the two entities is not necessary in order to initiate therapy.

In some patients with a symmetric inflammatory polyarthritis, the only clue to the diagnosis of psoriatic arthritis is a family history of psoriasis. However, in the majority, the findings of skin psoriasis, nail changes (onychodystrophy), sausage toes or fingers, oligoarticular asymmetric large joint or spinal involvement, and/or arthritis mutilans help distinguish the two entities. (See "Clinical manifestations and diagnosis of psoriatic arthritis".)

Polymyalgia rheumatica — Polymyalgia rheumatica (PMR) can sometimes be mistaken for RA in patients presenting with more limited arthritis over the age of 50 who are seronegative or have a low RF titer. Unlike RA, PMR is usually associated with marked myalgias in the shoulders and hips, and joint involvement tends to be milder, more limited, and more often asymmetric.

Stiffness is thus more axial in PMR and more likely to be described as difficulty getting out of bed, while stiffness in the small joints of the hands and other involved joints predominates in RA, in which difficulty buttoning clothing is more likely to be reported. However, similar complaints to RA may be present in patients with PMR with synovitis affecting the small joints in the hands.

The arthritis in PMR tends to respond strikingly to modest doses of glucocorticoids used to control other symptoms [30]. In patients initially diagnosed with PMR, persistent or recurrent small joint arthritis with tapering of glucocorticoids and the absence of other findings suggestive of PMR may lead to a change in the diagnosis to RA after several months or even years of treatment. (See "Clinical manifestations and diagnosis of polymyalgia rheumatica".)

Crystalline arthritis — Crystalline arthritis (gout and acute or chronic calcium pyrophosphate deposition disease [CPPD; pseudogout]) can become chronic and even assume a polyarticular distribution. The diagnosis is established by the finding of urate or calcium pyrophosphate crystals, respectively, in synovial fluids. The presence of tophi on physical examination, the lack of detection of serologic markers of RA, and the characteristic appearance of gouty erosions are also useful in distinguishing RA from polyarticular gout. Chondrocalcinosis on radiographs may be helpful in distinguishing CPPD from RA. Since crystalline arthritis is not uncommon, its presence does not exclude the diagnosis of RA. (See "Clinical manifestations and diagnosis of gout" and "Clinical manifestations and diagnosis of calcium pyrophosphate crystal deposition (CPPD) disease".)

Bacterial infectious arthritis

Lyme arthritis — Lyme arthritis, a late manifestation of Lyme disease, occurs primarily in individuals who live in or travel to Lyme disease-endemic areas. Lyme arthritis is characterized by intermittent or persistent inflammatory arthritis in a few large joints, most typically monoarthritis of the knee. The most commonly involved joints, after the knee, are the shoulder, ankle, elbow, temporomandibular joint, and wrist. Migratory arthralgias without frank arthritis may occur during early localized or early disseminated Lyme disease. (See "Musculoskeletal manifestations of Lyme disease".)

The diagnosis of Lyme arthritis can usually be made by serologic testing, which should be performed in patients presenting with undiagnosed inflammatory arthritis in endemic areas. In addition, several clinical features help distinguish Lyme arthritis from RA. Involvement of the small joints of the hands and feet is uncommon in patients with Lyme arthritis. Furthermore, many, but not all, patients with Lyme arthritis will describe an antecedent history of erythema migrans or other early disease manifestations. (See "Musculoskeletal manifestations of Lyme disease", section on 'Diagnosis of Lyme arthritis'.)

Other infectious arthritis — Infectious arthritis is usually monoarticular, but polyarthritis can occur. The diagnosis is established by culturing the pathogen from the synovial fluid or from the blood. Patients with septic arthritis may or may not appear toxic on examination, depending upon the stage of their infection, the presence of medications that can mask infection (eg, glucocorticoids), and other clinical variables. Peripheral blood leukocytosis with a left shift is common but not invariably present.

A low threshold for suspecting infection is required, particularly in compromised hosts. Patients with RA are at increased risk for joint infections because a damaged joint can serve as a nidus of infection. Synovial fluid changes, including marked granulocytosis and low glucose levels, are similar to those seen in RA. (See "Septic arthritis in adults".)

Hypermobility syndrome and fibromyalgia — Pain, rather than stiffness or swelling, is the dominant symptom of the two common disorders, hypermobility syndrome (which includes hypermobility spectrum disorder and hypermobility type Ehlers-Danlos syndrome) and fibromyalgia [31,32]. Although the hypermobility syndromes and fibromyalgia can both bear superficial resemblances to RA due to the presence of polyarthralgia, there are important distinguishing features:

- The hypermobility syndromes are associated with hyperextensible joints, and patients lack signs of synovitis. (See "Clinical manifestations and diagnosis of hypermobile Ehlers-Danlos syndrome and hypermobility spectrum disorder".)
- Fibromyalgia is associated with tender points at nonarticular sites and chronic widespread pain. However, there is no evidence of synovitis, such as swelling, warmth, or diminished joint range of motion, although patients may exhibit joint line tenderness on exam. (See "Clinical manifestations and diagnosis of fibromyalgia in adults".)
- Neither the hypermobility syndromes nor fibromyalgia are associated with significant titers of RF or ACPAs or with elevated levels of acute phase reactants.

Although RA is usually not difficult to distinguish from fibromyalgia, diagnostic confusion can arise when assessment of serologies or acute phase reactants is performed and modestly elevated results are observed that are of unclear significance. In addition, a significant minority of patients with RA also develop fibromyalgia. The source of complaints in such patients needs to be carefully assessed to distinguish heightened pain sensitivity from pain related to inflammatory joint disease.

Paraneoplastic and cancer treatment-related disease — Joint pain or frank polyarthritis can occur in association with cancer. The following are some examples:

- **Hypertrophic osteoarthropathy** – Patients with hypertrophic osteoarthropathy, sometimes termed hypertrophic pulmonary osteoarthropathy, typically demonstrate clubbing of the digits, joint pain, and periosteal new bone formation. Additionally, they give a characteristic history suggestive of bone pain and often describe the pain as deep and achy; nocturnal pain is common. Joint effusions may occur. (See "Malignancy and rheumatic disorders", section on 'Hypertrophic osteoarthropathy'.)

- **Myelodysplasia** – Patients with myelodysplastic syndrome sometimes develop an inflammatory polyarthritis that mimics RA [33]. The majority of patients are seronegative for RF and few are positive for anti-citrullinated peptide antibody or exhibit erosive changes on joint radiography. The arthritis may precede the diagnosis of myelodysplasia in at least half of the patients. In a cohort study of 87 patients with myelodysplastic syndrome, five (6 percent) had inflammatory arthritis that resembled RA [34]. Persistence of anemia, other cytopenias, or elevated acute phase reactants despite control of the arthritis should heighten suspicion of myelodysplasia [33]. (See "Clinical manifestations and diagnosis of myelodysplastic syndromes (MDS)".)

- **Immune checkpoint inhibitor therapy** – Cancer therapy that involves use of immune checkpoint inhibitor (ICI) immunotherapy may result in a number of rheumatologic and other adverse effects, including inflammatory arthritis that resembles RA. The joint symptoms may range from mild to severe and can develop at almost any time during ICI therapy. RF and ACPAs are often absent. (See "Rheumatologic complications of checkpoint inhibitor immunotherapy", section on 'Inflammatory arthritis'.)

Multicentric reticulohistiocytosis — Multicentric reticulohistiocytosis is a rare but highly destructive form of arthritis [35,36]. The rapid joint destruction of multicentric reticulohistiocytosis resembles the arthritis mutilans occasionally observed in RA. Multiple smooth, shiny, erythematous nodules located in the periungual region suggest multicentric reticulohistiocytosis. Binucleated or multinucleated foreign body type giant cells are present on skin or synovial biopsies in multicentric reticulohistiocytosis [37,38]. In a minority of patients, an underlying malignancy may be present. (See "Cutaneous manifestations of internal malignancy", section on 'Multicentric reticulohistiocytosis'.)

Multicentric reticulohistiocytosis is relatively resistant to glucocorticoids and to disease-modifying antirheumatic drugs (DMARDs) [35,36,39-42].

Sarcoid arthropathy — Chronic arthritis in sarcoidosis may be oligoarticular or polyarticular and can appear similar to RA in some patients. It most frequently affects the ankles, knees, hands, wrist, and MCP and PIP joints, and it is frequently associated with parenchymal pulmonary disease. (See "Sarcoid arthropathy".)

This disorder is distinguished from RA by the following findings:

- Elevated serum concentrations of angiotensin-converting enzyme (ACE) are found in up to 50 percent of patients.
- A chest radiograph may reveal characteristic findings of sarcoidosis.
- The pattern of acute arthritis with Lofgren's syndrome in patients with sarcoidosis is not observed in those with RA.

SOCIETY GUIDELINE LINKS

Links to society and government-sponsored guidelines from selected countries and regions around the world are provided separately. (See "Society guideline links: Rheumatoid arthritis".)

INFORMATION FOR PATIENTS

UpToDate offers two types of patient education materials, "The Basics" and "Beyond the Basics." The Basics patient education pieces are written in plain language, at the 5th to 6th grade reading level, and they answer the four or five key questions a patient might have about a given condition. These articles are best for patients who want a general overview and who prefer short, easy-to-read materials. Beyond the Basics patient education pieces are longer, more sophisticated, and more detailed. These articles are written at the 10th to 12th grade reading level and are best for patients who want in-depth information and are comfortable with some medical jargon.

Here are the patient education articles that are relevant to this topic. We encourage you to print or e-mail these topics to your patients. (You can also locate patient education articles on a variety of subjects by searching on "patient info" and the keyword(s) of interest.)

- Basics topics (see "Patient education: Rheumatoid arthritis (The Basics)")
- Beyond the Basics topics (see "Patient education: Rheumatoid arthritis symptoms and diagnosis (Beyond the Basics)" and "Patient education: Rheumatoid arthritis treatment (Beyond the Basics)")

SUMMARY AND RECOMMENDATIONS

- **Evaluation in patients suspected of RA** – Rheumatoid arthritis (RA) should be suspected in the adult patient who presents with inflammatory polyarthritis. The initial evaluation of such patients requires a careful history and physical examination,

along with selected laboratory testing to identify features that are characteristic of RA or that suggest an alternative diagnosis. (See 'Evaluation for suspected RA' above and 'Differential diagnosis' above.)

- **Components of the medical evaluation** – The following components of the medical evaluation are helpful in making a clinical diagnosis of RA, both for the identification of characteristic findings and for the exclusion of other diagnoses (see 'Evaluation for suspected RA' above):
  - **History** – A thorough medical history, with particular attention to joint pain, stiffness, and associated functional difficulties.
  - **Physical examination** – A complete physical examination to assess for synovitis, limited joint motion, extraarticular disease manifestations, and signs of diseases included in differential diagnosis.
  - **Laboratory testing** – Basic and selected laboratory testing, including assays for acute phase reactants (erythrocyte sedimentation rate [ESR] and C-reactive protein [CRP]), rheumatoid factor (RF), anti-citrullinated peptide antibodies (ACPAs), and antinuclear antibodies (ANA).
  - **Imaging** – Selected imaging studies, including bilateral radiographs of the hands, wrists, and feet.
  - **Role of arthrocentesis** – Arthrocentesis, if there is diagnostic uncertainty, to establish the presence of an inflammatory process within the joint and rule out other causes (eg, infection, crystal arthritis).
- **Diagnosis in patients with characteristic findings** – The diagnosis of RA can be made in a patient with inflammatory arthritis involving three or more joints, positive RF and/or anti-citrullinated peptide/protein antibody, disease duration of more than six weeks, and elevated CRP or ESR, but without evidence of alternative diagnoses with similar clinical features. (See 'Our diagnostic criteria' above.)
- **Diagnosis in patients without all of the classic findings** – RA may also be diagnosed in patients without all of the classic findings of disease. This includes patients with seronegative RA, those with clinically quiescent disease, and those with recent onset RA. Such patients have findings/clinical features that are generally consistent with those described as meeting the American College of Rheumatology (ACR)/European Alliance of Associations for Rheumatology (EULAR) classification criteria for RA. (See 'Patients not meeting above criteria' above.)

- **Classification criteria** – The 2010 ACR/EULAR classification criteria for RA were developed primarily for the identification for research purposes of patients with RA who are at high risk of persistent symptoms and joint injury unless treated with disease-modifying antirheumatic drugs (DMARDs). These criteria have replaced the 1987 criteria, which were based only upon patients with established disease. (See 'Classification criteria' above.)

- **Differential diagnosis** – The differential diagnosis of RA includes multiple disorders that can generally be distinguished by history, physical examination, and limited laboratory and radiographic testing, based upon evidence of the following features (see 'Differential diagnosis' above):

  - Evidence of osteoarthritis (table 2), carpal tunnel syndrome, or tendinopathy (suggesting a noninflammatory process)

  - Limited duration of symptoms (eg, in viral arthropathy)

  - The presence of other diseases (eg, in psoriatic arthritis or arthritis of inflammatory bowel disease [IBD])

  - The pattern of joint involvement and other symptoms (eg, in psoriatic arthritis, spondyloarthropathy, or polymyalgia rheumatica [PMR])

  - The presence of systemic features (eg, in systemic lupus erythematosus [SLE], sarcoidosis, or dermatomyositis [DM])

  - Diagnostic laboratory tests associated with other conditions (eg, specific autoantibodies in SLE, synovial fluid crystals in gout or calcium pyrophosphate disease)

  - Relatively high specificity of ACPAs for RA

Rheumatoid Arthritis Disease Activity Measures: American College of Rheumatology Recommendations for Use in Clinical Practice

JACLYN ANDERSON,[1] LIRON CAPLAN,[2] JINOOS YAZDANY,[3] MARK L. ROBBINS,[4] TUHINA NEOGI,[5] KALEB MICHAUD,[6] KENNETH G. SAAG,[7] JAMES R. O'DELL,[1] AND SALAHUDDIN KAZI[8]

Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide guidance for particular patterns of practice and not to dictate the care of a particular patient. The ACR considers adherence to these guidelines and recommendations to be voluntary, with the ultimate determination regarding their application to be made by the physician in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed or endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice.

The American College of Rheumatology is an independent, professional, medical and scientific society which does not guarantee, warrant, or endorse any commercial product or service.

Objective. **Although the systematic measurement of disease activity facilitates clinical decision making in rheumatoid arthritis (RA), no recommendations currently exist on which measures should be applied in clinical practice in the US. The American College of Rheumatology (ACR) convened a Working Group (WG) to comprehensively evaluate the validity, feasibility, and acceptability of available RA disease activity measures and derive recommendations for their use in clinical practice.**

Methods. **The Rheumatoid Arthritis Clinical Disease Activity Measures Working Group conducted a systematic review of the literature to identify RA disease activity measures. Using exclusion criteria, input from an Expert Advisory Panel (EAP), and psychometric analysis, a list of potential measures was created. A survey was administered to rheumatologists soliciting input. The WG used these survey results in conjunction with the psychometric analyses to derive final recommendations.**

Results. **Systematic review of the literature resulted in identification of 63 RA disease activity measures. Application of exclusion criteria and ratings by the EAP narrowed the list to 14 measures for further evaluation. Practicing rheumatologists rated 9 of these 14 measures as most useful and feasible. From these 9 measures, the WG selected 6 with the best psychometric properties for inclusion in the final set of ACR-recommended RA disease activity measures.**

Conclusion. **We recommend the Clinical Disease Activity Index, Disease Activity Score with 28-joint counts (erythrocyte sedimentation rate or C-reactive protein), Patient Activity Scale (PAS), PAS-II, Routine Assessment of Patient Index Data with 3 measures, and Simplified Disease Activity Index because they are accurate reflections of disease activity; are sensitive to change; discriminate well between low, moderate, and high disease activity states; have remission criteria; and are feasible to perform in clinical settings.**

Introduction

The last 2 decades have witnessed a dramatic improvement in the treatment of rheumatoid arthritis (RA), with disease remission now considered a realistic goal for many patients (1). Surrogate measures of outcome such as disease activity measures can facilitate clinical decision mak-

Significance & Innovations

- This study systematically examines published measures of disease activity in rheumatoid arthritis (RA), identifying those measures that are valid and feasible to perform in clinical settings.
- Incorporation of these validated RA disease activity measures into a practice's workflow will facilitate adherence to the American College of Rheumatology guidelines for the treatment of RA and provide the necessary tools for treating to target.
- Routine use of these measures will allow clinicians to demonstrate that they are providing high-quality care for RA, as measured by nationally endorsed quality measures.

ing to achieve these goals, and studies in RA show that treating to a target improves outcomes (2–4). As health care reform in the US accelerates efforts to improve quality, assessment of disease activity in RA has become a nationally endorsed quality measure. For example, the Physician Quality Reporting System, a pay-for-reporting program administered by the Centers for Medicare and Medicaid Services, includes a quality measure assessing whether physicians measure RA disease activity using a standardized scale or composite index and classify RA disease activity as low, moderate, or high at least yearly (5).

Despite the push from various stakeholders in the health care system to standardized disease activity assessment in RA and growing evidence that treating to target is effective, most US rheumatologists do not routinely use standardized measures in clinical practice. The myriad available instruments and lack of formal recommendations on which measures are best suited for different practice settings likely contribute to this lack of implementation. As a first and important step in addressing this issue, the American College of Rheumatology (ACR) commissioned a Working Group (WG) to use a validated multistep process to derive recommendations for the use of RA disease activity measures in clinical practice.

The goal of this effort was to determine which disease activity measures reliably distinguish between different levels of disease activity in RA and are feasible to implement in clinical practice. In this article, we review the methods for arriving at our recommendations, summarize the important components of the selected measures, and also discuss some of the practical issues that rheumatologists should consider in deciding which measure to implement in their practice setting.

Submitted for publication October 23, 2011; accepted in revised form February 14, 2012.

Materials and Methods

The methods used to derive our recommendations are summarized very briefly here, but are outlined in significantly greater detail in Supplementary Appendix A (available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658). Figure 1 shows an overview of the methodology used, which included a combination of a systematic literature review, psychometric analyses, validated group methods, and physician surveys.

First, the WG conducted a systematic literature review to identify available RA disease activity measurement tools and applied initial exclusion criteria (see Supplementary Figure 1 and Supplementary Table 1, available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658). Next, an RA disease activity measurement Expert Advisory Panel (EAP), consisting of rheumatologists with published expertise in RA disease activity measurement, was consulted to review measures meeting criteria for inclusion. The EAP ranked the recommended measures by using the Outcome Measures in Rheumatology filter on truth, discrimination, and feasibility (6). The WG then further condensed the number of measures based on a detailed review of the psychometric properties of each measure. The abbreviated measure set was then incorporated into a survey administered to practicing rheumatologists to gather information regarding usefulness, feasibility, and willingness to use in daily clinical practice. Collation of the information gathered in these steps formed the basis for the final WG recommendations.

Results

Systematic literature review and EAP ratings. Sixty-three tools to measure RA disease activity were initially identified, 16 of which met prespecified exclusion criteria (see Supplementary Figure 1 and Supplementary Table 1, available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658). From the remaining 47 measures, 4 were combined into 2 measures. Forty-five measures were then presented to members of the EAP, and ratings of familiarity with the measure, personal experience using the measure, and a final recommendation regarding use in clinical practice resulted in selection of 31 measures (see Supplementary Table 2, available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658).

Qualitative feedback from the EAP was then used to further abbreviate this list of measures, including recommendations to exclude instruments that primarily measure quality of life (n = 10), do not indicate the current state of

Groups responsible for each component of the project:
The Working Group (WG)
Expert Advisory Panel (EAP)
American College of Rheumatology members (rheumatologists)
Phase 1: literature review
Identify 63 available disease activity measurement tools; apply exclusion criteria to reduce list to 47 measures
Phase 2: electronic survey
Recommend which measures are best for clinical use by ranking 47 measures from phase 1
Phase 3: reduction of measures
Review EAP rankings and limit the number of phase 1 measures for further analysis; reduce list from 47 to 19 measures
Phase 4: detailed reporting for measures
Compile psychometric and time-to-complete data on the remaining 19 measures
Phase 5: electronic survey
Characterize the 14 measures by usefulness, feasibility, and willingness to use
Review survey, exclude 8 measures, and draft recommendations, which include 6 measures
Review and approve recommendations
American College of Rheumatology Quality Measures Subcommittee, Quality of Care Committee, and Board of Directors, with input from the Committee on Rheumatologic Care

Figure 1. Flow diagram of methods.

disease activity (i.e., require the calculation of change scores [n = 2]), are confined to a single body region (n = 1), or are antiquated and no longer in current use (n = 1).

Psychometric analyses. The remaining 19 measures were then subjected to a detailed review of psychometric properties, including evaluation of their reliability, validity, and responsiveness. Five measures were excluded in this phase based on the lack of defined remission and/or disease activity criteria. The psychometric analyses have been published previously in *Arthritis Care & Research* (7). Table 1 summarizes the psychometric properties of the 14 measures resulting from the steps above.

Membership survey. The 14 measures were then grouped (Disease Activity Score [DAS]/DAS with 28-joint counts [DAS28], Simplified Disease Activity Index [SDAI]/Clinical Disease Activity Index [CDAI], Patient Activity Scale [PAS] scores, Routine Assessment of Patient Index Data [RAPID] scores, Rheumatoid Arthritis Disease Activity Index 5, Chronic Arthritis Systemic Index, and patient global assessment of disease activity [PtGA]/provider global assessment of disease activity [PrGA]) and incorporated into a survey sent to practicing rheumatologists (n = 4,368); 335 recipients (7.7%) completed the survey. Most respondents (76.8%) were currently using a measurement tool in their clinical practice (see Supplementary Table 3, available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658). We weighted the survey results for region, sex, and age to adjust for the low response rate (see Supplementary Table 4, available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658).

Derivation of final recommendations. Based on the information gathered in the preceding phases, including psychometric analyses and physician ratings, the WG selected 6 measures for point-of-care RA disease activity

Table 1. Summary of RA disease activity measures recommended for point-of-care clinical use*

Measure/scale	Measure outputs	No. of items	Response format	Method of administration	Time for administration	Validated in RA	Psychometric properties†		
							Reliability	Validity	Responsiveness
Patient-driven composite tools									
PAS	A single score on a continuous scale (0–10)	3	HAQ: 0–3 Pain VAS: 0–10 Pt Global VAS: 0–10	Patient questionnaire	Patient: <3.5 minutes Provider: <1 minute Lab: N/A	Yes	Acceptable; test–retest reliability for composite has not been evaluated	Acceptable	Acceptable for individual components
PAS-II	A single score on a continuous scale (0–10)	3	HAQ-II: 0–3 Pain VAS: 0–10 Pt Global VAS: 0–10	Patient questionnaire	Patient: <1.5 minutes Provider: <30 seconds Lab: N/A	Yes	Acceptable; test–retest reliability for composite has not been evaluated	Acceptable	Acceptable for individual components
RAPID-3	A single score on a continuous scale (0–10)	3	MDHAQ: 0–3 Pain VAS: 0–10 Pt Global VAS: 0–10	Patient questionnaire	Patient: ≈1.5 minutes Provider: <30 seconds Lab: N/A	Yes	Acceptable; test–retest reliability for composite has not been evaluated	Good	Acceptable for individual components
Patient and provider composite tool									
CDAI	A single score on a continuous scale (0–76)	4	28TJC: 0–28 28SJC: 0–28 Pt Global VAS: 0–10 Pr Global VAS: 0–10	Provider item; patient item	Patient: ≈10 seconds Provider: <2 minutes Lab: N/A	Yes	Good; test–retest reliability for composite has not been evaluated	Excellent	Excellent
Patient, provider, and laboratory composite tools									
DAS28 (ESR or CRP)	A single score on a continuous scale (0–9.4)	4, or 3 when general health is omitted	28TJC: 0–28 28SJC: 0–28 ESR: 0–100 or CRP with lower detection level of 1.0 mg/liter Pt Global VAS: 0–100	Provider assessment; patient item; lab	Patient: ≈10 seconds Provider: 3–5 minutes Lab: 1 hour waiting time for ESR	Yes	Excellent	Excellent	Excellent
SDAI	A single score on a continuous scale (0–86)	5	28TJC: 0–28 28SJC: 0–28 Pt Global VAS: 0–10 CRP: 0–10	Provider item; patient item; lab	Patient: ≈10 seconds Provider: ≈2 minutes Lab: waiting time for CRP varies by lab	Yes	Good; test–retest reliability for composite has not been evaluated	Excellent	Excellent

* Measures are not shown in order of preference. RA = rheumatoid arthritis; PAS = Patient Activity Scale; HAQ = Health Assessment Questionnaire; VAS = visual analog scale; Pt Global VAS = patient global assessment of disease activity VAS; Lab = laboratory value required; N/A = not applicable; RAPID-3 = Routine Assessment of Patient Index Data with 3 measures; MDHAQ = Multidimensional HAQ; CDAI = Clinical Disease Activity Index; 28TJC = 28 tender joint count; 28SJC = 28 swollen joint count; Pr Global VAS = provider global assessment of disease activity VAS; DAS28 = Disease Activity Score with 28-joint counts; ESR = erythrocyte sedimentation rate; CRP = C-reactive protein; SDAI = Simplified Disease Activity Index.
† Psychometric properties were subjectively ranked using an ordered category scale (excellent, good, acceptable, poor, and unacceptable) based on currently published literature.

measurement: the CDAI, DAS28 (erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP]), PAS, PAS-II, RAPID-3, and SDAI (Table 2).

Discussion

Since the 1950s, when the first composite disease activity measurement tool for use in RA was developed (8), many attempts have been made to improve RA disease activity monitoring. Of the 63 currently available RA disease activity measurement tools, we used a multistep process to progressively filter down to 6 recommended measures: the CDAI, DAS28 (ESR or CRP), PAS, PAS-II, RAPID-3, and SDAI. All 6 produce a single continuous index and have defined ranges for indicating low, moderate, or high disease activity or clinical remission (Table 3). By applying these tools systematically in clinical practice, physicians will be able to "treat to target" and effectively implement the ACR recommendations for the treatment of RA (9).

Realizing the heterogeneity of settings in which health care is delivered to patients with RA in the US, we selected measures that offer a full range of data collection options. Some are purely patient reported (PAS, PAS-II, and RAPID-3), some add provider assessment (CDAI), and some add provider assessment and laboratory acute-phase reactants (SDAI and DAS28). Below we summarize the key features of each measure to allow those caring for patients with RA to select the one best suited to their clinical practice.

Patient-driven composite tools (PAS [10], PAS-II [10], and RAPID-3 [11]) have the advantage of being relatively easy to use in clinical practice because they do not require provider assessments such as formal joint counts (tender or swollen). Patients can often complete these measures on standardized paper or electronic forms in the waiting room, making them very practical to use.

There are 3 core components to each of the patient-driven measures: visual analog scale patient pain score (12), PtGA (12), and a measure of functional assessment. Since 2 of 3 components are similar across these measures, the distinguishing feature is the functional assessment tool (PAS includes the Health Assessment Questionnaire [HAQ] [13], PAS-II includes the HAQ-II [10,14], and RAPID-3 uses the Multidimensional HAQ [MDHAQ] [15]). In choosing a measure, providers may want to consider the length (the MDHAQ in RAPID-3 and the HAQ-II in PAS-II are 10 items each, while the original HAQ in PAS is 41 items) and psychometric properties of each functional assessment tool, discussed briefly below. For a more detailed review of the psychometric properties of the 3 patient-driven disease

Table 3. Disease activity cutoffs for each American College of Rheumatology–recommended disease activity measure*

Disease activity measure	Scale	Remission	Low/minimal	Moderate	High/severe
Patient-driven composite tools					
PAS	0–10	0.00–0.25	0.26–3.70	3.71 to <8.0	8.00–10.00
PAS-II	0–10	0.00–0.25	0.26–3.70	3.71 to <8.0	8.00–10.00
RAPID-3	0–10	0–1.0	>1.0 to 2.0	>2.0 to 4.0	>4.0 to 10
Patient and provider composite tool					
CDAI	0–76	≤2.8	>2.8 to 10.0	>10.0 to 22.0	>22.0
Patient, provider, and laboratory composite tools					
DAS28 (ESR or CRP)	0–9.4	<2.6	≥2.6 to <3.2	≥3.2 to ≤5.1	>5.1
SDAI	0–86	≤3.3	>3.3 to ≤11.0	>11.0 to ≤26	>26

* PAS = Patient Activity Scale; RAPID-3 = Routine Assessment of Patient Index Data with 3 measures; CDAI = Clinical Disease Activity Index; DAS28 = Disease Activity Score with 28-joint counts; ESR = erythrocyte sedimentation rate; CRP = C-reactive protein; SDAI = Simplified Disease Activity Index.

Table 4. Formulas for measurement tools*

Measurement tool	Formula	Online source
CDAI	28SJC + 28TJC + PrGA + PtGA	http://www.rheumatology.org/CDAI
DAS28		
DAS28-ESR	$0.56 \times \sqrt{(28TJC)} + 0.28 \times \sqrt{(28SJC)} + 0.70 \times \ln(ESR) + 0.014 \times PtGA$	http://www.das-score.nl/
DAS28-CRP	$0.56 \times \sqrt{(28TJC)} + 0.28 \times \sqrt{(28SJC)} + 0.36 \times \ln(CRP + 1) + 0.014 \times PtGA + 0.96$	http://www.das-score.nl/

PAS-II	(HAQ-II × 3.33 + pain VAS + PtGA VAS)/3	http://www.arthritis-research.org/research/pas
RAPID-3	(MDHAQ × 3.33 + pain VAS + PtGA VAS)/3	http://mdhaq.org/Public/Questionnaires.aspx
SDAI	28SJC + 28TJC + PrGA + PtGA + CRP	http://www.rheumatology.org/SDAI

* Numerical rating scales may be substituted for visual analog scales (VAS) in all measures. CDAI = Clinical Disease Activity Index; 28SJC = 28 swollen joint count; 28TJC = 28 tender joint count; PrGA = provider global assessment of disease activity; PtGA = patient global assessment of disease activity; DAS28 = Disease Activity Score with 28-joint counts; ESR = erythrocyte sedimentation rate; CRP = C-reactive protein; PAS = Patient Activity Scale; HAQ = Health Assessment Questionnaire; RAPID-3 = Routine Assessment of Patient Index Data with 3 measures; MDHAQ = Multidimensional HAQ; SDAI = Simplified Disease Activity Index.

activity measures, please refer to the recent assessment by Anderson et al (7).

All 3 measures take less than 3 minutes for patients to complete and have simple mathematical scoring. However, the RAPID-3 has been tested in many rheumatic diseases, not just RA, and therefore may be applied to patients more broadly in clinic practice. Beyond these practical issues, there are other issues related to the reliability and validity of these measures that should be considered. For example, although components of each of the 3 measures have been found to be reliable, valid, and sensitive to change, information is not available about how the composite score for each measure performs. Additionally, long-term outcomes regarding joint damage with these 3 measures have not been studied directly. Therefore, it is theoretically possible that the composite score may be less reliable, valid, or sensitive to change than its individual components.

Finally, patient-driven tools lack a formal joint assessment, something that is thought to lend face validity to a measure of RA disease activity (2). However, it is important to realize that the inclusion of provider joint counts is highly examiner dependent, and while fairly reproducible by a single assessor, may be unreliable if the assessor changes and may not correlate completely with sonographic evidence of synovitis (16,17). While patient-reported measures have important limitations, such as reflecting a patient's perception of their disease, which may be influenced by a variety of factors (e.g., cultural beliefs, self-efficacy, mood), they do produce a less random and more reliable measurement of change over time. In addition, some studies suggest that patient-reported measures predict long-term outcomes better than provider joint counts and acute-phase reactants (18–21). The formulas used to calculate each measurement tool are shown in Table 4.

The CDAI, a patient and provider composite tool (22), adds 3 components of the provider assessment (PrGA, 28 swollen joint count, and 28 tender joint count) to the PtGA. Designed as a simple numerical addition of the component scores, it avoids point-of-care issues such as needing a calculator to enter differentially weighted components. Further, it does not require an acute-phase reactant, enhancing its feasibility in some clinical settings since results are available in real time. The measure does require providers to perform detailed joint counts reliably and consistently.

Available studies show excellent psychometric properties, including validity and sensitivity to change. Although the components are reliable, it should be noted that the reliability of the composite measure is unknown.

The patient, provider, and laboratory composite tools (SDAI [23] and DAS28 [24]) have several components in common: provider tender and swollen joint counts, PtGA, and an acute-phase reactant. The main distinctions between these 2 measures are that the DAS28 does not include a PrGA and it requires a more complex calculation to arrive at a score based on differential weighting of individual indices (e.g., the DAS28 weighs tender joint count more heavily than swollen joint count).

The SDAI (like the CDAI) is a simpler numerical addition of individual components that are weighted evenly. Generally, the DAS28 uses the ESR (although the DAS28-CRP is also available) and the SDAI uses the CRP level. The SDAI is the most sensitive and specific for prediction of clinical decisions to change disease-modifying antirheumatic drugs, and an SDAI score $\leq$3.3 is one of two recommended definitions of remission by the ACR and the European League Against Rheumatism to be used in RA clinical trials (1). Although remission criteria for the DAS28 are less conservative than several other measures, including both the SDAI and CDAI, treating to a DAS28 target level of $\leq$2.4 has been shown to improve RA outcomes (3,25).

It is important to note that the inclusion of acute-phase reactants in these measures introduces a new set of variables, and therefore adds some complexity. The ESR contributes a sizeable portion (15%) of the information in the DAS28-ESR. Therefore, remission may be underestimated in high ESR states with few active joints. Similarly, in low ESR states, remission criteria may be met but patients may still have a significant number of swollen joints (26,27). Like the DAS28-ESR, it has been shown that DAS28-CRP scores may also incorrectly estimate remission as they are

generally lower than DAS28-ESR scores (28). Another consideration is that newer biologic agents that target specific inflammatory cytokines are differentially reflected in the ESR and CRP and may therefore disproportionately deflate the composite score.

In addition, inclusion of acute-phase reactants in the DAS28 and SDAI complicates the logistics and timing of using these measures in point-of-care clinical decision making. Although these measures have traditionally been used in clinical trials, academic medical centers, and large multispecialty clinics, logistical barriers have likely delayed their widespread adoption in smaller practice settings.

ACR members responding to our survey rated the PtGA and PrGA as the most feasible tools for use in clinical practice. However, these measures are not included in the final set of selected measures. Limitations of these measures include the lack of standardization in structure (e.g., horizontal and vertical visual analog scale, anchored versus unanchored lines, boxes or circles) and the paucity of well-defined disease activity categories, which are important in creating thresholds for clinical decision making and for quality reporting.

The WG recognizes that there is currently no ideal measure of disease activity, and acknowledges that some measures excluded in our review may later be found to possess adequate, or even superior, psychometric properties to the 6 recommended measures. In the absence of head-to-head comparisons of the different disease activity tools, we had to rely on a process that involved a combination of expert opinion and literature review to select measures. Nevertheless, based on available evidence and expert opinion, we believe we have identified measures that are currently the most reliable, valid, feasible, and acceptable measures of disease activity in RA.

It is important to note that we made no attempt to perform de novo psychometric analyses on measures and restricted our work to reviewing published literature. In addition, our survey of the ACR membership had a low response rate. This may signal that few clinicians currently measure RA disease activity systematically, or that most feel unqualified to rate the utility of different measurement tools. To partially address the low response rate, we weighted the characteristics of the responders versus those of nonresponders for region, sex, and age. These weighted responses suggest that the responders were generally representative of the ACR membership on the examined characteristics.

Finally, although remission is the ultimate therapeutic goal in RA, remission and even attainment of low disease activity may not be appropriate targets for all patients due to comorbid conditions, treatment toxicity, and patient preference. In addition, some measure components are influenced by comorbid conditions that elevate acute-phase reactants or result in tender joints (e.g., fibromyalgia) (2). Despite these complexities, standardized assessment of disease activity in RA facilitates treating to target, which has been shown to improve disease outcomes (2).

The CDAI, DAS28 (ESR or CRP), PAS, PAS-II, RAPID-3, and SDAI all accurately reflect disease activity; are sensitive to change; discriminate between low, moderate, and high disease activity states; are feasible to perform at the point of care; and are acceptable to most practicing rheumatologists. Above we have outlined our methods for arriving at these recommended measures and summarized some of the key features that clinicians should consider when choosing a measure to adopt in their clinical practice. Incorporation of these validated RA disease activity measures into a practice's workflow will facilitate adherence to the ACR guidelines for the treatment of RA and provide the necessary tools for treating to target. Moreover, routine use of these measures will allow clinicians to demonstrate that they are providing high-quality care for RA, as measured by nationally endorsed quality measures.

ACKNOWLEDGMENTS

We thank Harlan Sayles, University of Nebraska Medical Center, Omaha, Nebraska, for statistical analysis of the member survey, and all those who participated in the surveys performed as part of this project. We also thank Amy Miller, American College of Rheumatology, Atlanta, Georgia, for editorial assistance.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Dr. Kazi had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

oped, in 3 phases, a new approach to classifying RA. The work focused on identifying, among patients newly presenting with undifferentiated inflammatory synovitis, factors that best discriminated between those who were and those who were not at high risk for persistent and/or erosive disease—this being the appropriate current paradigm underlying the disease construct "rheumatoid arthritis."

Results. **In the new criteria set, classification as "definite RA" is based on the confirmed presence of synovitis in at least 1 joint, absence of an alternative diagnosis that better explains the synovitis, and achievement of a total score of 6 or greater (of a possible 10) from the individual scores in 4 domains: number and site of involved joints (score range 0–5), serologic abnormality (score range 0–3), elevated acute-phase response (score range 0–1), and symptom duration (2 levels; range 0–1).**

Conclusion. **This new classification system redefines the current paradigm of RA by focusing on features at earlier stages of disease that are associated with persistent and/or erosive disease, rather than defining the disease by its late-stage features. This will refocus attention on the important need for earlier diagnosis and institution of effective disease-suppressing therapy to prevent or minimize the occurrence of the undesirable sequelae that currently comprise the paradigm underlying the disease construct "rheumatoid arthritis."**

Introduction

Rheumatoid arthritis (RA) is a chronic inflammatory disease characterized by joint swelling, joint tenderness, and destruction of synovial joints, leading to severe disability and premature mortality (1–5). Given

the presence of autoantibodies, such as rheumatoid factor (RF) and anti–citrullinated protein antibody (ACPA) (tested as anti–cyclic citrullinated peptide [anti-CCP]), which can precede the clinical manifestation of RA by many years (6–9), RA is considered an autoimmune disease (10,11). Autoimmunity and the overall systemic and articular inflammatory load drive the destructive progression of the disease. However, although structural changes, which can be visualized by conventional radiography or other imaging techniques, best distinguish RA from other arthritic disorders (12), joint damage is rarely apparent in the very early stages of disease, but rather accumulates consistently over time (13–16).

Over the last decade, the optimal use of disease-modifying antirheumatic drugs (DMARDs), in particular the anchor DMARD methotrexate (MTX) (17–19), and the availability of new biologic agents (11,20), have dramatically enhanced the success of RA management. Moreover, it has been recognized that early therapeutic intervention improves clinical outcomes and reduces the accrual of joint damage and disability (21–23). Undoubtedly, treating patients at a stage at which evolution of joint destruction can still be prevented would be ideal. However, at present, clinical trials of RA treatments are hampered by lack of criteria allowing for study enrollment of patients at early stages of disease. Thus, to date it has not been possible to effectively investigate the efficacy of early interventions in terms of their ability to prevent later-stage RA, since there are no validated or accepted uniform criteria to classify such individuals with early disease.

The standard and accepted means of defining RA is by use of classification criteria. Classification criteria enable the stratification of groups of individuals into those with and those without RA in order to standardize recruitment into clinical trials and related studies, and provide the basis for a common approach to disease definition that can be used to compare across studies and centers. The classification criteria set that is in widespread international use to define RA is the 1987 American College of Rheumatology (ACR; formerly the American Rheumatism Association) criteria (24). These criteria are well accepted as providing the benchmark for disease definition, but have a significant limitation in that they were derived by trying to discriminate patients with established RA from those with a combination of other definite rheumatologic diagnoses. They are therefore not helpful in achieving the goal of identifying patients who would benefit from *early* effective intervention, as discussed above. Indeed, with modern therapies, the goal is to prevent individuals from reaching the chronic, erosive disease state that is exemplified in the 1987 criteria for RA.

A joint working group of the ACR and the European League Against Rheumatism (EULAR) was therefore formed to develop a new approach for classification of RA. While classification criteria are potentially adopted for use as aids for diagnosis, the focus of this endeavor was not on developing diagnostic criteria or providing a referral tool for primary care physicians. Indeed, a separate body of work is needed to develop such tools, which may be informed by classification criteria. Thus, the specific charge was to develop new classification criteria for RA to facilitate the study of persons at earlier stages of the disease. It was with this framework in mind that the working group developed the 2010 ACR/EULAR classification criteria for RA.

Overview on hypothesis and methods of Phases 1 and 2

A priori, the working group focused on developing an approach that would be appropriate for newly presenting patients with undifferentiated inflammatory synovitis, in order to identify that subset of patients who are at sufficiently high risk of persistent and/or erosive disease—this being the appropriate current paradigm underlying the disease construct "rheumatoid arthritis"—to be classified as having RA. It was recognized that such a scheme should not be developed using existing criteria sets as the "gold standard," because of the inherent circularity. The goal set forth was to develop a set of rules to be applied to newly presenting patients with undifferentiated synovitis that would 1) identify the subset at high risk of chronicity and erosive damage; 2) be used as a basis for initiating disease-modifying therapy; and 3) not exclude the capture of patients later in the disease course.

To achieve these goals, the working group devised a 3-phase program. Phase 1 was a data-driven approach based on cohorts of real-world patients with early arthritis, to identify factors, and their relative weights, that were associated with the subsequent decision by a physician to start MTX treatment. Phase 2 was a consensus-driven, decision science–based approach, informed by the data from Phase 1, to refine these factors and their weights using a series of "paper patients," as well as to identify any other factors that may be of relevance based on current clinical thinking. Phase 3, which is the focus of this report, describes the derivation, from the previous 2 phases, of the final

Table 1. Summary of Phase 1 results*

Variable	Comparison	Relative weight†
Swollen MCP joint	Present vs. absent	1.5
Swollen PIP joint	Present vs. absent	1.5
Swollen wrist	Present vs. absent	1.6
Hand tenderness	Present vs. absent	1.8
Acute-phase response	Low-level abnormal vs. normal	1.2
	Highly abnormal vs. normal	1.7
Serology	Low-positive vs. negative	2.2
(RF or ACPA)	High-positive vs. negative	3.9

* MCP = metacarpophalangeal; RF = rheumatoid factor; ACPA = anti–citrullinated protein antibody.
† Derived from odds ratios from the multivariate regression model, and interpreted as the increase in the odds of having rheumatoid arthritis (RA) with as opposed to without the respective feature (e.g., weight of 1.5 for swelling of proximal interphalangeal [PIP] joints means that the odds of having RA is 1.5-fold in patients with as opposed to patients without swelling of a PIP joint).

classification criteria set. The details of the methods and results from Phases 1 and 2 are provided elsewhere (25,26), and are briefly summarized below.

Phase 1. The aim of Phase 1 was to identify the contributions of clinical and laboratory variables that in practice were the most predictive of the decision to initiate DMARD therapy in a population of patients with early undifferentiated synovitis. Initiation of DMARD therapy was used as an indicator of the physician's opinion that the patient was at risk of developing persistent and/or erosive arthritis that we would currently consider to be RA. Data on 3,115 patients from 9 early arthritis cohorts who were considered not to have evidence of another possible diagnosis explaining their presentation were obtained. Between July 2007 and November 2008 an expert working group developed an analysis strategy that related an agreed-upon list of standardized clinical and laboratory variables collected at baseline to the initiation of DMARD treatment within the next 12 months. MTX initiation was used as the gold standard for this purpose. The analytical process aimed to identify the independent contribution of each variable on this list and included univariate regression modeling, a subsequent principal components analysis, and a multivariate regression model that included all identified components (25). The resulting list of informative variables identified during that process and the weights based on the odds ratios are shown in Table 1.

Phase 2. Phase 2 consisted of a consensus-based, decision science–informed approach, which took place between November 2008 and June 2009. The purpose of this phase was to derive a clinician-based judgment on the relative contribution of clinical and laboratory factors deemed to be important in influencing the probability of developing "persistent inflammatory and/or erosive arthritis that is currently considered to be RA" (hereinafter referred to as "developing RA").

An expert panel was assembled, comprising 12 rheumatologists from Europe and 12 from North America with extensive experience in the diagnosis and management of RA. They provided real-life case scenarios of patients with early undifferentiated inflammatory arthritis representing low to high probability of developing RA. A 2-day workshop was held in May 2009 in which domains (factors) and categories within those domains that were important in determining the probability of developing RA were identified. When appropriate, these judgments were informed by the results of Phase 1 and other available literature. The relative importance or weights of these domains and their categories were determined by means of decision science theory and conjoint adaptive technology, using the computerized 1000Minds program (www.1000minds.com) in an interactive and iterative process (26). This analysis permitted the calculation of an individual's score of the likelihood of developing RA from 0 to 100, where a higher score indicated greater likelihood of RA development. The domains, categories, and weights derived during that initial process are shown in Table 2.

Objectives, methods, and results of Phase 3

Objectives of Phase 3. In Phase 3 the working group integrated the findings of the first 2 phases, refined the scoring system, and determined the optimal cut point to define "definite RA." The goal of this final phase was to utilize the results of Phases 1 and 2 to develop a scoring system that would be applicable to *newly* presenting patients with undifferentiated inflammatory arthritis to permit identification of those with a high probability of developing persistent and/or erosive RA. Being intended for use with newly presenting patients, the scoring system should be robust enough that it could be applied repeatedly during the early course of disease, such that a patient identified as not classifiable as having definite RA at initial presentation might be classified as having definite RA at a subsequent time point. The work was not aimed at classifying subjects with established disease, either active or inactive. However, the working group recognized that patients may present for the first time with disease that is at a later stage and being treated. Thus, although it was not the explicit charge of the working group to provide

Table 2. Summary of Phase 2 results and subsequent modifications

	Exact (0−100)	Rescaled (0−10)	Rounded to 0.5 (0−10)
Joint involvement*			
1 large	0	0	0
>1−10 large, asymmetric	10.2	1.02	1
>1−10 large, symmetric	16.1	1.61	1.5
1−3 small	21.2	2.12	2
4−10 small	28.8	2.88	3
>10, including at least 1 small joint	50.8	5.08	5
Serology†			
Negative RF *and* negative ACPA	0	0	0
Low-positive RF *or* low-positive ACPA	22.0	2.20	2
High-positive RF *or* high-positive ACPA	33.9	3.39	3.5
Acute-phase reactants‡			
Normal CRP *and* normal ESR	0	0	0
Abnormal CRP *or* abnormal ESR	5.9	0.59	0.5
Duration of symptoms§			
<6 weeks	0	0	0
≥6 weeks	9.3	0.93	1

* Joint involvement refers to any *swollen* or *tender* joint on examination. Distal interphalangeal joints, first carpometacarpal joints, and first metatarsophalangeal joints are *excluded from assessment*. Categories of joint distribution are classified according to the location and number of the involved joints, with placement into the highest category possible based on the pattern of joint involvement. "Large joints" refers to shoulders, elbows, hips, knees, and ankles. "Small joints" refers to the metacarpophalangeal joints, proximal interphalangeal joints, second through fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists. "Symmetric" is defined as bilateral involvement of at least 1 region. In the category ">10 joints," at least 1 of the involved joints must be a small joint; the other joints can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (e.g., temporomandibular, acromioclavicular, sternoclavicular, etc.).

† Negative refers to IU values that are less than or equal to the upper limit of normal (ULN) for the laboratory and assay; low-positive refers to IU values that are higher than the ULN but ≤3 times the ULN for the laboratory and assay; high-positive refers to IU values that are >3 times the ULN for the laboratory and assay. Where rheumatoid factor (RF) information is only available as positive or negative, a positive result should be scored as low-positive for RF. ACPA = anti−citrullinated protein antibody.

‡ Normal/abnormal is determined by local laboratory standards. CRP = C-reactive protein; ESR = erythrocyte sedimentation rate.

§ Duration of symptoms refers to patient self-report of the duration of signs or symptoms of synovitis (e.g., pain, swelling, tenderness) of joints that are clinically involved at the time of assessment, regardless of treatment status.

rules for the classification of such patients, it is appropriate to have a single criteria system that could be applied to all patients; these issues were addressed by the expert panel during Phase 3.

Determination of the optimal cut point for definite rheumatoid arthritis. Determination of the optimal cut point to classify an individual as having definite RA was achieved using 2 complementary approaches, mirroring the approaches used in the first 2 phases: data-informed and consensus-based. From the consensus-based approach, the expert panel was asked to examine the rankings of case scenarios based on the new scoring system and to indicate, in their opinion, the point at which the cases changed from "probable" to "definite" RA. Four cases were excluded due to missing domain information (n = 2) or ineligibility (2 cases were more likely another diagnosis). For the remaining 50 cases, the mean cut point defining definite RA was 65.7 (median 66.1; range 60.0–70.3) of a total possible score of 100.

A data-driven verification of that cut point was then attempted, in which the new scoring system was applied to 3 of the existing cohorts used for Phase 1 (the Etude et Suivi des Polyarthrites Indifferenciees Recentes data set from France, the Norwegian data set, and the Rotterdam Early Arthritis Cohort data set from Rotterdam) (25). These cohorts were chosen based on the completeness of data and the collected variables, enabling calculation of the patients' probability scores at baseline. The disease characteristics of these cohorts were not substantively different from those of the remaining cohorts (data not shown).

The area under the curve (AUC) for the 3 receiver operating characteristic (ROC) curves (which plot sensitivity against 1 − specificity for the range of scores) indicated good discrimination of those who did versus those who did not receive MTX (or another DMARD/biologic agent) within a year (AUC 0.82 for Norway, 0.66 for France, and AUC 0.69 for Rotterdam; $P < 0.0001$ for all). The probability scores similarly discriminated between those who fulfilled the 1987 ACR criteria at 12 months and those who did not (AUC for the ROC curves 0.88 [Norway], 0.67 [France], and 0.72 [Rotterdam]). Visual inspection of the diagnostic test parameters associated with curves that used MTX initiation as the outcome showed a maximum slope for both the positive and negative likelihood ratios between a score of 60/100 and 70/100, with flattening thereafter (67 in the Norway cohort, 66 in the French cohort, and 66 in the Rotterdam cohort). The cut point of 60–70 that was derived from expert consensus was therefore supported by these data. Given the consistency with the consensus-based approach, and to maximize sensitivity of the criteria, a cut point of 60 was deemed to be most appropriate.

Rationale for the composition and weight of the final criteria. For development of the final criteria set, the results and weights from the comprehensive Phase 2 process (26) were used as a starting point. Based on

Table 3. The 2010 American College of Rheumatology/European League Against Rheumatism classification criteria for rheumatoid arthritis

	Score
Target population (Who should be tested?): Patients who	
1) have at least 1 joint with definite clinical synovitis (swelling)*	
2) with the synovitis not better explained by another disease†	
Classification criteria for RA (score-based algorithm: add score of categories A–D; a score of ≥6/10 is needed for classification of a patient as having definite RA)‡	
A. Joint involvement§	
1 large joint¶	0
2−10 large joints	1
1−3 small joints (with or without involvement of large joints)#	2
4−10 small joints (with or without involvement of large joints)	3
>10 joints (at least 1 small joint)**	5
B. Serology (at least 1 test result is needed for classification)††	
Negative RF *and* negative ACPA	0
Low-positive RF *or* low-positive ACPA	2
High-positive RF *or* high-positive ACPA	3
C. Acute-phase reactants (at least 1 test result is needed for classification)‡‡	
Normal CRP *and* normal ESR	0

≥6 weeks	1

* The criteria are aimed at classification of newly presenting patients. In addition, patients with erosive disease typical of rheumatoid arthritis (RA) with a history compatible with prior fulfillment of the 2010 criteria should be classified as having RA. Patients with longstanding disease, including those whose disease is inactive (with or without treatment) who, based on retrospectively available data, have previously fulfilled the 2010 criteria should be classified as having RA.

† Differential diagnoses vary among patients with different presentations, but may include conditions such as systemic lupus erythematosus, psoriatic arthritis, and gout. If it is unclear about the relevant differential diagnoses to consider, an expert rheumatologist should be consulted.

‡ Although patients with a score of <6/10 are not classifiable as having RA, their status can be reassessed and the criteria might be fulfilled cumulatively over time.

§ Joint involvement refers to any *swollen* or *tender* joint on examination, which may be confirmed by imaging evidence of synovitis. Distal interphalangeal joints, first carpometacarpal joints, and first metatarsophalangeal joints are *excluded from assessment*. Categories of joint distribution are classified according to the location and number of involved joints, with placement into the highest category possible based on the pattern of joint involvement.

¶ "Large joints" refers to shoulders, elbows, hips, knees, and ankles.

"Small joints" refers to the metacarpophalangeal joints, proximal interphalangeal joints, second through fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists.

** In this category, at least 1 of the involved joints must be a small joint; the other joints can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (e.g., temporomandibular, acromioclavicular, sternoclavicular, etc.).

†† Negative refers to IU values that are less than or equal to the upper limit of normal (ULN) for the laboratory and assay; low-positive refers to IU values that are higher than the ULN but ≤3 times the ULN for the laboratory and assay; high-positive refers to IU values that are >3 times the ULN for the laboratory and assay. Where rheumatoid factor (RF) information is only available as positive or negative, a positive result should be scored as low-positive for RF. ACPA = anti−citrullinated protein antibody.

‡‡ Normal/abnormal is determined by local laboratory standards. CRP = C-reactive protein; ESR = erythrocyte sedimentation rate.

§§ Duration of symptoms refers to patient self-report of the duration of signs or symptoms of synovitis (e.g., pain, swelling, tenderness) of joints that are clinically involved at the time of assessment, regardless of treatment status.

these categories and weights, we aimed in the final steps of the project to simplify the criteria in order to ensure that they were user friendly. We used the results of the data-driven Phase 1 as a guide for these adaptations, and verified at each step that the main properties of the criteria were not altered and that classification of patients remained unchanged.

The general steps toward simplification are shown

in Table 2, and included rescaling the scoring system to a scale of 0–10. Then, each of the category weights was rounded to multiples of 0.5. We tested the rounded scoring system in the case scenarios that had been used in Phase 2, and found no changes in the ranking of the cases compared with the exact scale. According to the rescaling, the cut point for definite RA would be ≥6/10.

Despite their slightly different weights, the categories of asymmetric and symmetric oligoarthritis of large joints were merged for several reasons: first, symmetry was not found to be significantly important in the data analysis during Phase 1 (25), and second, the impact of merging was minimal when all possible presentations of patients with symmetric or asymmetric large joint inflammation were explored. For simplicity and ease of use, an integer scale was sought for all components of the scoring system. Thus, the high positive serology category was rounded from 3.5 (originally 3.39) to an integer of 3 because in no instance would classification status be altered by this change. Additionally, the weight for abnormal acute-phase response was rounded from 0.5 (originally 0.59) to 1, based on the stronger weight of acute-phase response (and of high-level acute-phase response) in Phase 1 (25).

Validation of the final criteria set. The final criteria set with its simplified scoring system was further validated. Using the Phase 2 patient case scenarios, the correlation between cases' mean derived probability scores (0–100) and the proportion of expert panel members who indicated that they would initiate treatment with MTX out of concern about risk for persistence and/or erosive damage was strong (Spearman's r = 0.82, $P < 0.0001$). The correlation of score with the proportion of experts who would refer the patient to a trial of a new biologic agent with inherent risks was similarly strong (Spearman's r = 0.0.85, $P < 0.0001$).

As a further validation, 3 cohorts that were not used in the identification of factors from Phase 1 were studied (Leiden [The Netherlands], Leeds [UK], and Toronto [Canada]); their characteristics were not substantively different from those of the remaining cohorts (25). Among cohort participants who received MTX within a year from symptom onset, the proportions with a score of ≥6/10 were 96.8% (Leiden), 90.5% (Leeds), and 87.2% (Toronto).

Eligibility for testing with the new criteria. The classification criteria can be applied to any patient or otherwise healthy individual, as long as 2 mandatory requirements are met: first, there must be evidence of currently active clinical synovitis (i.e., swelling) in at least 1 joint as determined by an expert assessor (Table 3). All joints of a full joint count may be assessed for this purpose with the exception of the distal interphalangeal (DIP) joints, the first metatarsophalangeal (MTP) joint, and the first carpometacarpal (CMC) joint, since these joints are typically involved in osteoarthritis. Although currently no methods other than clinical examination should be used to evaluate the presence of synovitis in this determination of eligibility, this may change in the future as validated imaging techniques become more widely available. Second, the criteria may be applied only to those patients in whom the observed synovitis is not better explained by another diagnosis (Table 3). For example, conditions that should be considered and excluded include systemic lupus erythematosus, psoriatic arthritis, and gout, among others.

Classification criteria for RA. Four additional criteria can then be applied to eligible patients, as defined above, to identify those with "definite RA"; these are shown in Table 3. Application of these criteria provides a score of 0–10, with a score of ≥6 being indicative of the presence of definite RA. This final scoring system was derived from both Phase 1 and Phase 2 data. A patient with a score below 6 cannot be classified as having definite RA, but might fulfill the criteria at a later time point. Figure 1 depicts a tree algorithm that incorporates the weights of each domain and the cut point of 6 for classification as definite RA. To classify a patient as having or not having definite RA, a history of symptom duration, a thorough joint evaluation, and at least 1 serologic test (RF or ACPA) and 1 acute-phase response measure (erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP]) must be obtained. It is acknowledged that an individual patient may meet the definition of RA without requiring that all tests be performed. For example, patients with a sufficient number of joints involved and longer duration of symptoms will achieve 6 points regardless of their serologic or acute-phase response status. However, for the purposes of clinical research and trial enrollment, documentation of each domain will be necessary for phenotyping.

Other clinical presentations: erosions and late disease. Because the aim of the new classification criteria is to enable diagnosis and treatment earlier in the course of disease to prevent disease complications, erosions were not considered for inclusion in the scoring system. However, as stated above, the working group recognized that patients may present at later stages of disease. Additionally, a single criteria system that could be applied to all patients was desired. Therefore, in addition to those who are newly presenting, 3 other

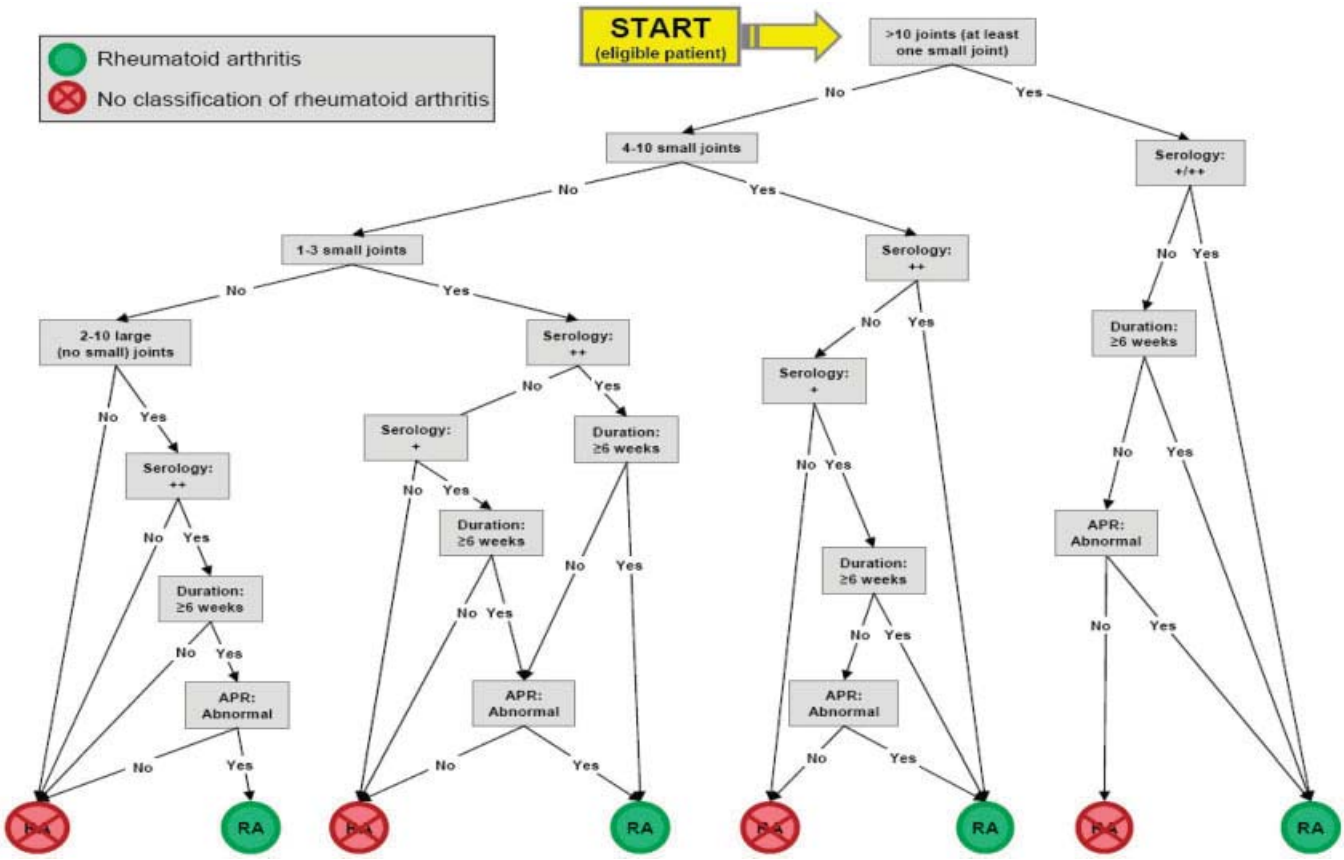

Figure 1. Tree algorithm for classifying definite rheumatoid arthritis (RA) (green circles) or for excluding its current presence (red circles) among those who are eligible to be assessed by the new criteria. APR = acute-phase response. Serology: + = low-positive for rheumatoid factor (RF) or anti–citrullinated protein antibody (ACPA); serology: ++ = high-positive for RF or ACPA; serology: +/++ = serology either + or ++. See footnotes to Table 3 for further explanation of categories.

groups of patients had to be considered: 1) those with erosions typical for RA were deemed to have prima facie evidence of RA and can be classified as such; 2) those with longstanding disease, either active or inactive, who, based on retrospectively available data, can be determined to have previously satisfied the classification criteria can similarly be classified as having definite RA; and 3) in the setting of early disease that is being treated, subjects may not fulfill the new criteria at initial presentation, but may do so as their condition evolves over time.

Glossary of definitions

In this section, we provide the detailed definitions necessary to correctly and accurately apply the new classification criteria for RA. A brief version of the glossary is included in the footnotes to Table 3.

Definition of an "involved" joint. Joint involvement, as used for the determination of pattern of joint distribution, differs from the definition of synovitis in 1 joint needed for eligibility in the eligibility criteria (see above): here it refers to any joint with swelling or tenderness on examination that is indicative of active synovitis. Tenderness is included as an equally important feature as swelling for the determination of joint involvement, particularly for the second through fifth MTP joints, in order to maximize sensitivity. Again, the DIP joints, the first MTP joint, and the first CMC joint should not be considered, given their prevalent involvement in osteoarthritis. Further, any joints with known

recent injury that could contribute to swelling or tenderness should not be considered. Additional evidence of joint activity from other imaging techniques (such as magnetic resonance imaging or ultrasound) may be used for confirmation of the clinical findings.

Definition of small joints. Small joints include the metacarpophalangeal, proximal interphalangeal (PIP), second through fifth MTP, and thumb IP joints, and the wrists. They do not include the first CMC, first MTP, or DIP joints, which are often affected by osteoarthritis.

Definition of large joints. The term "large joints" refers to the shoulders, elbows, hips, knees, and ankles.

Determination of the joint pattern category. Patients are categorized according to the number and location of involved joints by placing them into the category with the highest possible score. For example, a patient with involvement of 2 large joints and 2 small joints is placed in the category "1–3 small joints," as this category has the higher score. Patients should be scored for their joint involvement assuming that all of the peripheral joints indicated above have been assessed. For the highest category of joint involvement, in which >10 joints must be involved (including at least 1 small joint), additional joints that can be considered for inclusion in this count include the temporomandibular joint, sternoclavicular joint, acromioclavicular joint, and others that may be reasonably expected to be involved in RA.

Definition of the serologic categories. ACPA and IgM-RF levels are usually reported in IU. Based on the upper limit of normal (ULN) for the respective laboratory test and assay the following definitions can be made: *negative* = less than or equal to the ULN for the laboratory test and assay; *low-level positive* = higher than the ULN but ≤ 3 times the ULN for the laboratory test and assay; *high-level positive* = >3 times the ULN for the laboratory test and assay. Where RF information is available only qualitatively or as a level, and thus positive or negative, patients with a positive level should be scored as "low-level positive" for RF. Where a value for a serologic test is not available *or* the normal range is not available for the reported test value, the result for that test should be considered "negative/normal." Patients should be scored only if information from at least 1 serologic test is available.

Definition of abnormal acute-phase response. The acute-phase response measures CRP or ESR are scored as normal or abnormal based on the local laboratory standards. If results of at least 1 of these 2 tests are abnormal, the patient should be scored as having an abnormal acute-phase response. If a value for an acute-phase reactant is not available *or* information on the normal range for the reported test value is not available, the result of that test should be considered "negative/normal." For ESR, a standard approach that considers age and sex differences would be valuable. Patients should be scored only if at least 1 acute-phase response test is available for scoring.

Definition of duration of symptoms. The "duration of symptoms" domain refers to the patient's self-report of the maximum duration of signs or symptoms of synovitis (pain, swelling, and tenderness) of any joint that is clinically involved at the time of assessment (i.e., the day the criteria are applied). Thus, joints that are reported to have been previously symptomatic but are not involved at the time of assessment, whether due to treatment or not, should not be considered in estimating symptom duration.

Discussion

We present here new classification criteria for rheumatoid arthritis, representing the culmination of an international collaborative effort supported by both a data-driven and a consensus-based approach. This classification scheme is designed to present a standardized approach to identifying that subset of individuals who present with an otherwise unexplained inflammatory arthritis of a peripheral joint(s), for whom the risk of symptom persistence or structural damage is sufficient to be considered for intervention with DMARDs. This is thus the new proposed paradigm for the entity "rheumatoid arthritis"—importantly, not criteria for "early" RA. If there was an intervention that was both infinitely effective and safe and could be provided at no cost and no discomfort, then there would be no requirement for such a subset to be identified, as every patient with inflammatory arthritis would be treated. Given that such an intervention does not exist, the search for appropriate classification rules is justified, and will also be helpful in guiding clinical diagnosis.

It is important, however, to stress that the criteria are meant to be applied only to eligible patients, in whom the presence of obvious *clinical* synovitis in at least 1 joint is central. They should not be applied to patients with mere arthralgia or to normal subjects. However, once definite clinical synovitis has been determined (or historical documentation of such has been obtained), as indicated in the glossary, a more liberal approach is allowed for determining number and distri-

bution of involved joints, which permits inclusion of tender or swollen joints.

Symmetry is not a feature of the new criteria since it did not carry an independent weight in any phase of the work. Inevitably, though, the greater the number of involved joints the higher the likelihood of bilateral involvement.

The development of these new criteria was based on diverse study cohorts and was performed by RA experts of diverse nationalities, enhancing the criteria set's generalizability. The final criteria also reflect consistency in domains of importance through use of 2 independent methodologies. Previous classification schemes centered on a pre-identified clinical concept, typified by the occurrence of a predominantly symmetric small joint polyarthritis associated with autoantibody production and a high prevalence of erosions (27). This was the "gold standard" used to devise the rules that could be applied in a repeatable manner to identify homogeneous groups for observation and study. The new criteria redefine RA, reflecting our collective hope that in the future, RA will no longer be characterized by erosive joint disease and persistence of symptoms, although these characteristics will continue to define established or longstanding untreated disease. This reflects several conceptual issues that are relevant in all areas of research and also in clinical practice.

Once the disease entity is redefined, existing epidemiologic data on prevalence will have less relevance. Generally, this should not be a major concern, since there are well-recognized difficulties in gathering and interpreting epidemiologic data regarding occurrence of RA: prevalence estimates are influenced by the effects of therapy and therefore are inherently unstable. The prevalence of RA could variously be described as the proportion of the population who have satisfied the new criteria at some relevant point in time.

The greater problem is the extrapolation of current literature on clinical trials and the design of future trials. The working group recommends that clinical trials should henceforth apply these new criteria; however, results from studies using the new criteria cannot necessarily be directly compared with the extensive body of existing work. In reality, in most trials, even of recent-onset RA, subjects with much higher levels of disease activity than is needed for fulfillment of the new criteria, and often those who have been treated unsuccessfully with multiple prior therapies, are selected (28). Thus, comparison between trials will be based much more on the distribution of disease activity at entry, for example, than the assumption that criteria satisfaction leads to homogeneity in patients recruited. Still, it might be useful, over this transition to the new criteria, for researchers to document the proportions of study subjects who fulfill the previous (1987) and the new RA classification criteria, to enable comparisons.

There is a potential problem related to the pursuit of basic research. For example, genetic association studies have relied on a standardized approach to phenotypic assessment based on the 1987 ACR criteria. Such association studies still hold and, as stated above, the new criteria are likely to be easily satisfied by the participants in such studies. RA is always considered a heterogeneous disorder, and the new criteria scheme will probably increase that heterogeneity. Thus, basic scientists should be aware and, where appropriate, restrict recruitment or stratify results based on clinically meaningful phenotypes. For example, even among patients fulfilling the 1987 criteria, those who are ACPA positive and those who are ACPA negative have been shown to differ from a pathogenetic, clinical, and prognostic perspective (29).

The criteria have been intentionally derived from paper patient cases and cohorts of newly presenting subjects with undifferentiated inflammatory synovitis. Once classified, unless an alternative explanation for the synovitis becomes apparent over time, the subject is labeled as having "definite RA." However, acknowledging that RA is not a static disease, the new criteria have been developed such that they can be applied to patients at more than one time point in the evolution of their symptoms and signs. Thus, a patient who does not fulfill criteria for definite RA at first presentation might be classified as having definite RA at a subsequent time point.

Rather than developing a parallel system for "established" disease or continuing to use the 1987 criteria for that purpose, the working group recommends that, when patient records allow, application of the criteria and assignment as definite RA may be made retrospectively. If there is a history compatible with definite RA as defined by these new criteria but no records of such, significant erosive disease seen on radiographs, typical of destructive RA, can be used as prima facie evidence of RA, precluding the need for applying additional criteria. Such individuals would need to be included as part of the total population of individuals affected by RA. It was not part of the working group's mission to define what is meant by significant erosive disease either in terms of the size, site, or number of erosions. Such agreement could be the task for further consensus, although current evidence sug-

gests that such a definition should be highly specific (30). Thus, future work will be needed to define what evidence of erosions is acceptable to be considered as "typical" of RA. This was a similar issue faced with the 1987 ACR criteria, but it did not detract from the usability of those criteria.

The use of the new criteria should be limited to a target population in whom there is otherwise no explanation (i.e., definite diagnosis) for their synovitis. The working group has deliberately not provided an exhaustive list of diagnoses or tests that should be performed to exclude these, since that is not the purpose of classification criteria. Differential diagnosis is a physician responsibility and will be influenced by patient age and sex, practice type, as well as variations in the background population in terms of the incidence of "competing" disorders. Thus, Lyme arthritis may be a frequent cause of synovitis in endemic areas, but testing for *Borrelia burgdorferi* would not be appropriate elsewhere. In this respect, the important utility of appropriate exclusion assessment is avoidance of misclassifying patients as having RA who might otherwise not need to be treated or have self-limiting disease.

It was not the charge of the working group to create a referral tool for primary care physicians. Indeed, the original 1987 ACR criteria were also not designed for such use. Primary care physicians and other specialists need an easy-to-use tool to facilitate identification of individuals who have an inflammatory arthritic syndrome and for whom referral to a rheumatologist for further evaluation and diagnosis is appropriate. Support for such an endeavor is already being undertaken as a joint effort by ACR/EULAR and other important stakeholders.

One limitation of the new criteria is that they are based on current knowledge. Genetic, proteomic, serologic, or imaging biomarkers that provide a more robust basis for risk stratification may emerge, and this would necessarily lead to a modification or amendment of the 2010 criteria. Similarly, biomarkers, including imaging modalities, that more robustly identify high-risk subgroups of patients with synovitis may one day be available and validated. A pertinent example of a new biomarker is ACPA (typically, with testing for anti-CCP). Based on a detailed literature review (31) and our analytical approach to physician decision-making, ACPA status did not add importantly to the ability to classify an individual as having RA, beyond the information provided by RF when it is positive. The working group has therefore included both markers (ACPA and RF) equally in the criteria. However, as ACPA testing becomes more standardized, further refinement may be needed.

Because there is no gold standard for a diagnosis of RA, the cutoff score of ≥ 6 is the best estimate from the current approaches used; testing in other cohorts will provide further evidence regarding its validity. Since the classification scheme actually provides a continuum of "risk for developing persistent and/or erosive RA" (i.e., it assigns the risk or probability of developing RA on a continuous score (from 0 to 100%), there is scope for investigators to use other cut points—or multiple cut points—for different purposes. For example, in a clinical trial of a new potentially toxic agent, a higher, more conservative, cut point might be more appropriate; this is akin to clinical trials enrolling patients who meet criteria but also have evidence of a certain degree of severity or extent of involvement. In contrast, a population study of familial aggregation might use a less restrictive cut point. As such, there is information derived from scores across the range from 0 to 10 that may be utilized for different purposes in the future.

The working group has deliberately labeled these criteria as "classification criteria" as opposed to "diagnostic criteria." The aim is to provide a standardized approach for discriminating, from a population of individuals presenting with undifferentiated synovitis, the subgroup with the highest probability of persistent or erosive RA, who may be enrolled into clinical trials and other studies through the use of uniform criteria. These individuals are also the ones who may therefore benefit from DMARD intervention. The criteria do not remove the onus on individual physicians, especially in the face of unusual presentations, to reach a diagnostic opinion that might be at variance from the assignment obtained using the criteria. Nonetheless, it is recognized that the new criteria will likely also be used as a diagnostic aid and be required to be satisfied, for example, by health care providers to enable access to particular interventions. However, much like other classification criteria, clinicians may be able to diagnose an individual who has not met the classification criteria definition or who has features that are not a component of the classification criteria. Diseases often present a much wider spectrum in clinical medicine that can be expected to be captured by classification criteria, the purpose of which is simply to provide a uniform set of standards by which an individual can be classified as having a clinical entity or not.

The new criteria need to be tested in several clinical situations and settings. Physicians need to report particularly if there is an important proportion of newly

presenting patients who do not satisfy these criteria but for whom there is a compelling reason to treat with a DMARD, or who on followup, *without* a change in their classification status develop persistent or erosive disease. Validation in 3 of the cohorts available to us showed that the criteria were satisfied in 87–97% of the patients in whom the physicians chose to initiate MTX treatment.

In summary, the new ACR/EULAR classification criteria for RA present a new approach with a specific emphasis on identifying patients with a relatively short duration of symptoms who may benefit from early institution of DMARD therapy or entry into clinical trials of promising new agents that may halt the development of disease that currently fulfills the 1987 ACR criteria.

ACKNOWLEDGMENTS

We are grateful to Celina Alves, Carly Cheng, Tracey Farragher, Elisabeth Hensor, Jolanda Luime, Klaus Machold, Maria Dahl Mjaavatten, Valerie Nell, Nathalie Rincheval, Marleen van de Sande, and Annette van der Helm-van Mil, who were involved in the development, data management, or maintenance of their respective data sets used in Phase 1 of the project, and to Rohit Aggarwal, Dinesh Khanna, Katherine Liao, Raj Nair, and Sarah Ringold, who were involved in the design or implementation of Phase 2. We also wish to thank the ACR and the EULAR for their financial support of this project. We are especially grateful to Amy Miller and Regina Parker from the ACR and Heinz Marchesi and Anja Schönbächler from the EULAR, for their administrative support of the project.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Dr. Silman had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study conception and design. Aletaha, Neogi, Silman, Felson, Birnbaum, Bykerk, Combe, Costenbader, Dougados, Emery, Hazes, Huizinga, Kay, Kvien, Moreland, Naden, Smolen, Stanislawska-Biernat, Vencovský, Hawker.

Acquisition of data. Aletaha, Neogi, Silman, Bingham, Birnbaum, Burmester, Bykerk, Combe, Costenbader, Dougados, Emery, Hazes, Huizinga, Kavanaugh, Kay, Kvien, Laing, Ménard, Naden, Smolen, Stanislawska-Biernat, Tak, Upchurch, Vencovský, Hawker.

Analysis and interpretation of data. Aletaha, Neogi, Silman, Funovits, Bingham, Birnbaum, Burmester, Bykerk, Cohen, Combe, Dougados, Emery, Ferraccioli, Hazes, Hobbs, Huizinga, Kay, Laing, Mease, Ménard, Moreland, Naden, Pincus, Smolen, Stanislawska-Biernat, Symmons, Tak, Upchurch, Vencovský, Wolfe, Hawker.

Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide guidance for particular patterns of practice and not to dictate the care of a particular patient. The ACR considers adherence to the recommendations within this guideline to be voluntary, with the ultimate determination regarding their application to be made by the physician in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed and endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. ACR recommendations are not intended to dictate payment or insurance decisions. These recommendations cannot adequately convey all uncertainties and nuances of patient care.

The ACR is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

This article is published simultaneously in *Arthritis & Rheumatology*.

Dr. Singh has received consulting fees, speaking fees, and/or honoraria from Savient, Allergan, Regeneron, Merz, Iroko, and Bioiberica (less than $10,000 each) and from Takeda and Dinora (more than $10,000 each), and has received grant/research support from Horizon. Dr. Saag has received consulting fees, speaking fees, and/or honoraria from Abbott, Amgen, Bayer, Bristol-Myers Squibb, Lilly, Merck, Pfizer, and Roche/Genentech (less than $10,000 each) and from Ardea/AstraZeneca (more than $10,000). Dr. Curtis has received con-

Objective. **To develop a new evidence-based, pharmacologic treatment guideline for rheumatoid arthritis (RA).**
Methods. **We conducted systematic reviews to synthesize the evidence for the benefits and harms of various treatment options. We used the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology to rate the quality of evidence. We employed a group consensus process to grade the strength of recommendations (either strong or conditional). A strong recommendation indicates that clinicians are certain that the benefits of an intervention far outweigh the harms (or vice versa). A conditional recommendation denotes uncertainty over the balance of benefits and harms and/or more significant variability in patient values and preferences.**
Results. **The guideline covers the use of traditional disease-modifying antirheumatic drugs (DMARDs), biologic agents, tofacitinib, and glucocorticoids in early (<6 months) and established (≥6 months) RA. In addition, it provides recommendations on using a treat-to-target approach, tapering and discontinuing medications, and the use of biologic agents and DMARDs in patients with hepatitis, congestive heart failure, malignancy, and serious infections. The guideline addresses the use of vaccines in patients starting/receiving DMARDs or biologic agents, screening for tuberculosis in patients starting/receiving biologic agents or tofacitinib, and laboratory monitoring for traditional DMARDs. The guideline includes 74 recommendations: 23% are strong and 77% are conditional.**
Conclusion. **This RA guideline should serve as a tool for clinicians and patients (our two target audiences) for pharmacologic treatment decisions in commonly encountered clinical situations. These recommendations are not prescriptive, and the treatment decisions should be made by physicians and patients through a shared decision-making process taking into account patients' values, preferences, and comorbidities. These recommendations should not be used to limit or deny access to therapies.**

INTRODUCTION

Rheumatoid arthritis (RA) is the most common autoimmune inflammatory arthritis in adults (1). RA has a significant negative impact on the ability to perform daily activities, including work and household tasks, and health-related quality of life, and it increases mortality (2–4). The American College of Rheumatology (ACR) last published a guideline for RA management in 2012 (5), which was an update of the 2008 RA guideline (6).

Because there has been rapid accrual of evidence and new therapies, advancement of guideline development methodologies, and the need to broaden the scope of its 2012 RA recommendations, the ACR has developed a new 2015 RA pharmacologic treatment guideline. This guideline addresses 6 major topics: 1) use of traditional disease-modifying antirheumatic drugs (traditional/conventional DMARDs, herein referred to as DMARDs), biologic DMARDs (herein referred to as biologics), and tofacitinib, including tapering and discontinuing medications, and a treat-to-target approach; 2) use of glucocorticoids; 3) use of biologics and DMARDs in high-risk populations (i.e., those with hepatitis, congestive heart failure, malignancy, and serious infections); 4) use of vaccines in patients starting/receiving DMARDs or biologics; 5) screening for tuberculosis (TB) in the context of biologics or tofacitinib; and 6) laboratory monitoring for traditional DMARDs.

METHODS

Overall methodology. We developed this guideline following the recently revised ACR guideline development process (http://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines). This process includes the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) methodology (available at www.gradeworkinggroup.org) (7–9).

Teams involved. A Core Leadership Team (see Appendix A for a list of Panel and Team members) supervised the project and was responsible for defining the project scope, drafting the clinical questions to be addressed by the guideline, coordinating with the Literature Review Team's efforts, and drafting the manuscript based on vot-

sulting fees, speaking fees, and/or honoraria from Pfizer, Bristol-Myers Squibb, Crescendo, and AbbVie (less than $10,000 each) and from Roche/Genentech, UCB, Janssen, the Consortium of Rheumatology Researchers of North America (CORRONA) registry, and Amgen (more than $10,000 each). Dr. Furst has received consulting fees, speaking fees, and/or honoraria from AbbVie, Actelion, Amgen, Bristol Myers Squibb, Cytori, Janssen, Gilead, GlaxoSmithKline, Novartis, Pfizer, Roche/Genentech, and UCB (less than $10,000 each) and has received research support from AbbVie, Actelion, Amgen, Bristol-Myers Squibb, Gilead, GlaxoSmithKline, Novartis, Pfizer, Roche/Genentech, and UCB. Dr. Kavanaugh has received consulting fees, speaking fees, and/or honoraria from Amgen, AbbVie, and Pfizer (less than $10,000 each) and grant/research support from Amgen, AbbVie, Bristol-Myers Squibb, Janssen, UCB, Roche, and Pfizer. Dr. O'Dell has received consulting fees, speaking fees, and/or honoraria from Medac, Antaes, AbbVie, Bristol-Myers Squibb, and Lilly (less than $10,000 each). Dr. King receives indirect sponsor payments as Medical Director of the North Mississippi Arthritis and Research Center. Ms Leong has received consulting fees, speaking fees, and/or honoraria from Horizon, GlaxoSmith-Kline, and Zimmer (less than $10,000 each). Dr. Matteson receives royalties from UpToDate, and has received grant/research support from Roche, Genentech, Mesoblast, Ardea, Novartis, Sanofi, Centocor, Janssen, Celgene, UCB, and GlaxoSmithKline. Dr. Grober has received consulting fees, speaking fees, and/or honoraria from Medac (less than $10,000). Dr. St.Clair owns stock or stock options from Bristol-Myers Squibb, Merck, and Proctor & Gamble, receives royalties from UpToDate, and has received grant/research support from Biogen. Dr. McAlindon has received consulting fees, speaking fees, and/or honoraria from Sanofi-Aventis, Samumed, Fidia, Flexion, and McNeil Consumer Healthcare (less than $10,000 each) and has a patent on an online clinical trial methodology through Boston University Medical School.

Submitted for publication March 19, 2015; accepted in revised form October 14, 2015.

ing by a panel (described below). The Core Leadership Team was led by a chair (JAS) who possessed both content and methodologic expertise. The Core Leadership Team also included a methodologist (EAA), who advised on the process and provided input on the GRADE summary of findings tables (see Evidence Report as part of Supplementary Appendix 1 available on the *Arthritis Care & Research* web site at http://onlinelibrary.wiley.com/doi/10.1002/acr.22783/abstract), and experts in guideline development. A Literature Review Team (see Appendix A for a list of Panel and Team members) conducted the literature review, graded the quality of evidence, developed the summary of findings tables, and produced an evidence report. A Content Panel, composed of 4 content experts (see Appendix A for a list of Panel and Team members) reviewed and provided feedback on the clinical questions and the evidence report, and provided consultation throughout the project. Finally, a Voting Panel (see Appendix A for a list of Panel and Team members) helped determine which clinical questions would be asked and which outcomes were critical, and they voted on the final recommendations after reviewing the evidence provided by the Literature Review Team. The Voting Panel included rheumatologists with expertise and clinical experience in treating RA (AK, JOD, CK, ELM, JTS, BD, JG, EWSC, ET), as well as 2 patient representatives (AL, SG). Training was conducted with all members of the guideline development group to prepare them for their roles, including specific sessions on the ACR guideline process and GRADE methodology.

Disclosures and management of conflicts of interest. In accordance with ACR policy, everyone who was intellectually involved in the project (i.e., considered for guideline authorship) disclosed all relationships in writing at the beginning, middle, and end of the project. Disclosures were compared against a previously drafted list of "affected companies" (i.e., companies or organizations that were considered reasonably likely to be positively or negatively affected by care delivered in accordance with the guideline) to determine which relationships were considered conflicts of interest for purposes of this project. Individuals whose primary employment (>51% of work time/effort) was with a company that manufactured or sold therapeutics or diagnostics were not eligible to participate.

The project Principal Investigator (JAS) and Literature Review Team Leader (TM) had no relevant conflicts of interest for the full 12 months before this project began, and a majority (>51%) of all guideline development team members, including the Principal Investigator and Literature Review Team Leader, had no relevant conflicts of interest for the duration of the project. A participant who had any relationship with an affected company was counted as conflicted (i.e., toward the allowed threshold) regardless of the type or subject of the relationship. Intellectual conflicts, such as a prior publication or presentation on an RA therapeutic, were recognized as important and were required to be disclosed, but because they were ubiquitous, participants with intellectual conflicts were not counted as conflicted (i.e., toward the allowed threshold) based on their intellectual conflict alone.

Participant disclosures were included in the project plan that was posted online for public comment (see description below). In addition, disclosures of all participants were shared with each project participant in writing. At the face-to-face Voting Panel meeting, verbal disclosures were provided before any content discussion. Updated participant disclosures, as well as ACR committee reviewer disclosures, are available online (www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines/Rheumatoid-Arthritis). Author disclosures are detailed in the footnotes of this article.

Scope and target audience. The Core Leadership Team decided that the guideline would address topics concerning the treatment of RA and not address any topics related to diagnosis, monitoring of disease activity, surgical interventions, or physical therapy interventions. The target audience includes both clinicians and their patients with RA. The ACR plans to develop derivative products in the future, including a pocket card, an app version of this guideline, and a patient education tool to facilitate implementation.

Establishing key principles and PICO (population, intervention, comparator, and outcomes) development. Key principles and provisos, key terms, descriptions, and drug categories used in the guideline development process are shown in Table 1. These key principles were first reviewed by the Content Panel and the Core Leadership Team. The key principles were then provided to the Voting Panel when they reviewed the drafted evidence report, and also when they discussed and voted on each recommendation. The Core Leadership Team collaborated with the Content Panel to develop the initial set of PICO-formatted clinical questions for the guideline (10). We considered clinically relevant interventions and comparators after extensive discussion with the Content Panel and the Core Leadership Team, balancing comprehensiveness with feasibility. These PICO questions were posted for 30 days on the ACR web site for public comment, and revised accordingly. The final set of PICO questions addressed the 6 major topics listed above.

Systematic synthesis of the literature. *Literature searches.* We performed systematic searches of the published literature to identify relevant evidence for the PICO questions (11). Study designs in the literature review included systematic reviews, randomized controlled trials (RCTs), and observational studies (including case series). We searched OVID Medline, PubMed, Embase, and the Cochrane Library (including Cochrane Database of Systematic Reviews; Database of Abstracts of Reviews of Effects; Cochrane Central Register of Controlled Trials; and Health Technology Assessments) (see Supplementary Appendix 2 available on the *Arthritis Care & Research* web site at http://onlinelibrary.wiley.com/doi/10.1002/acr.22783/abstract) (11). The searches were performed using database-specific subject headings and keywords related to the following domains of interest: RA, traditional/conventional DMARDs, tumor necrosis factor inhibitor (TNFi) biologics (adalimumab, certolizumab pegol, etanercept, golimumab, or infliximab), non-TNF biologics (abatacept, rituximab, or tocilizumab), tofacitinib, glucocorticoids, and adverse events. We limited our searches to adults ages

Table 1. Key provisos and principles, key terms, definitions, and drug categories for the 2015 ACR recommendations for the treatment of rheumatoid arthritis*

Key provisos and principles

1. Focus on common clinical scenarios, not exceptional cases.
2. Cost is a consideration in these recommendations; however, explicit cost-effectiveness analyses were not conducted.
3. Disease activity measurement using an ACR-recommended measure should be performed in a majority of encounters for RA patients (16).†
4. Functional status assessment using a standardized, validated measure should be performed routinely for RA patients, at least once per year, but more frequently if disease is active. Examples of commonly used functional status measures include Health Assessment Questionnaire, Health Assessment Questionnaire II, Multidimensional Health Assessment Questionnaire, PROMIS (available at https://www.assessmentcenter.net/) Physical Function 10-item, PROMIS Physical Function 20-item, and PROMIS Physical Function Computerized Adaptive Tests (PROPFCAT).
5. If a patient has low RA disease activity or is in clinical remission, switching from one therapy to another should be considered only at the discretion of the treating physician in consultation with the patient. *Arbitrary switching between RA therapies based only on a payer/insurance company policy is not recommended*.
6. A treatment recommendation favoring one medication over another means that the preferred medication would be the recommended first option. However, favoring one medication over the other does not imply that the nonfavored medication is contraindicated for use in that situation; it may still be a potential option under certain conditions.

Key terms	Definitions
Adult RA patient	Adults, ≥18 years, meeting the ACR RA classification criteria (1987 or 2010 revised criteria) (81,82).
Health benefits and harms	Efficacy and safety of treatments including desirable and undesirable effects.
Early RA	RA with duration of disease/symptoms of <6 months, where "duration" denotes the length of time the patient has had symptoms/disease, not the length of time since RA diagnosis.
Established RA	RA with duration of disease/symptoms of ≥6 months or meeting 1987 ACR RA classification criteria (81).‡
Disease activity	Categorized as low, moderate, or high as per validated scales (Table 2) (144–150). Moderate and high disease activity categories were combined based on feedback from the Content Panel, as used previously for the 2012 ACR RA treatment recommendations.
RA remission	A joint ACR/EULAR task force defined remission as a tender joint count, swollen joint count, C-reactive protein level (mg/dl), and patient global assessment of ≤1 each or a Simplified DAS of ≤3.3 (151), 1 of 6 ACR-endorsed disease activity measures.†
Optimal dosing of RA treatments	1) Dosing to achieve a therapeutic target derived from mutual patient-clinician consideration of patient priorities, and 2) given for at least 3 months before therapy escalation or switching.
DMARD failure	Failure of traditional/conventional DMARD(s) due to lack of efficacy/desired response or side effects.
Biologic failure	Failure of biologic(s) due to lack of efficacy/desired response or side effects.
Secondary biologic failure	Biologic was efficacious initially but subsequently became inefficacious.
Active hepatitis B infection	Hepatitis B surface antigen positive, hepatitis B surface antibody negative, hepatitis B core antibody total positive (less important), AST/ALT typically increased, HBV DNA positive (if checked).
Hepatitis C infection	HCV antibody positive, HCV RNA positive, AST/ALT typically increased.
NYHA class III and IV	NYHA class III includes patients with cardiac disease resulting in marked limitation of physical activity with less than ordinary physical activity causing fatigue, palpitation, dyspnea, or angina, but no symptoms at rest. NYHA class IV includes patients with cardiac disease resulting in inability to carry on any physical activity without discomfort, symptoms of heart failure are present even at rest, and discomfort increases if any physical activity is undertaken (152).

Drug category	Descriptions
Methotrexate	Used either oral or subcutaneous (a DMARD).
DMARDs§	Traditional/conventional DMARDs including HCQ, LEF, MTX, or SSZ (excludes azathioprine, cyclosporine, minocycline and gold), it does not include tofacitinib, which is considered separately.¶
DMARD monotherapy	Most often defined as the use of MTX monotherapy, but may also be SSZ, HCQ, or LEF.
Double DMARD therapy	MTX+SSZ, MTX+HCQ, SSZ+HCQ, or combinations with LEF.

(continued)

Table 1. *(Cont'd)*

Drug category	Descriptions
Triple DMARD therapy	MTX+SSZ+HCQ.
DMARD combination therapy	Double or triple traditional/conventional DMARD therapy.
Tofacitinib	Oral synthetic small molecule.
Biologics	TNFi biologic or non-TNF biologic (excludes anakinra).§
TNFi biologics	Adalimumab, certolizumab pegol, etanercept, golimumab, or infliximab.
Non-TNF biologics	Abatacept, rituximab, or tocilizumab (excludes anakinra).§
Low-dose glucocorticoid	≤10 mg/day of prednisone (or equivalent).
High-dose glucocorticoid	>10 mg/day of prednisone (or equivalent) and up to 60 mg/day with a rapid taper.#
Short-term glucocorticoid	<3 month treatment.

* ACR = American College of Rheumatology; RA = rheumatoid arthritis; PROMIS = Patient-Reported Outcomes Measurement Information System; EULAR = European League Against Rheumatism; DAS = Disease Activity Score; DMARD = disease-modifying antirheumatic drug; AST = aspartate aminotransferase; ALT = alanine aminotransferase; HBV = hepatitis B virus; HCV = hepatitis C virus; NYHA = New York Heart Association; HCQ = hydroxychloroquine; LEF = leflunomide; MTX = methotrexate; SSZ = sulfasalazine; TNFi = tumor necrosis factor inhibitor; COBRA = Combinatietherapie Bij Reumatoide Artritis.
† Any of the ACR recommended disease activity measures may be chosen, as described in ref. 16.
‡ New classification criteria for RA (ACR/EULAR collaborative initiative) were published in 2010 (82), the definition of established RA is based on the 1987 ACR RA classification criteria, since the 2010 ACR RA classification allows a much earlier diagnosis.
§ Anakinra was considered but not included in these guidelines due to its infrequent use in RA and lack of new data since 2012.
¶ Azathioprine, cyclosporine, minocycline and gold were considered but not included in these guidelines due to their infrequent use in RA and/or lack of new data since 2012.
# Regimen based on that described in the COBRA study (153).

≥18 years and to English language publications. Duplicate references were removed. We excluded narrative reviews, editorials, scientific conference abstracts, and case reports.

The literature related to treatment modalities covered by past ACR RA guidelines (i.e., traditional/conventional DMARDs, TNFi and non-TNF biologics) and tofacitinib was searched to include articles published from January 1, 2009 through March 3, 2014. For other treatment modalities not covered by past ACR RA guidelines (i.e., glucocorticoids), we searched the databases from inception until March 3, 2014. We updated initial literature searches on September 17, 2014. All searches were developed by a medical librarian in collaboration with the Literature Review Team and were peer reviewed by a second medical librarian.

Study selection. The literature search results underwent primary screening in DistillerSR software (Evidence Partners). During primary literature screening, 2 reviewers (various pairs, made from a pool of reviewers including authors MCS, EV, CM, and MO, as well as the medical librarian) independently reviewed the title and abstract of each article for potential eligibility. A third reviewer (RRB) resolved conflicts regarding inclusion versus exclusion. Articles judged as potentially eligible were tagged for electronic matching to specific PICO questions, and subsequently underwent full-text article screening. Each full text was screened by 2 reviewers and independently tagged with PICO-matching criteria. A secondary hand sorting of all randomized studies was conducted to ensure successful matching of relevant evidence to PICO questions (for details on the study selection see Supplementary Appendix 3 available on the *Arthritis Care & Research* web site at http://onlinelibrary.wiley.com/doi/10.1002/acr.22783/abstract).

Data extraction and analysis. We extracted study data for each PICO question into RevMan software (12). When determining which data to include, we followed the GRADE methodology that gives preference to RCTs over observational studies as the highest-quality source of evidence. Whenever data from both randomized and observational trials were available, and the RCT was of high quality, we extracted RCT data only (13). A RevMan file was created for each PICO question, and data were pooled and analyzed using this software. Continuous outcome variables were analyzed using the inverse variance method in a random effects model. Continuous outcomes were reported as mean differences with 95% confidence intervals; standardized mean differences (similar in concept to effect sizes) were used when the outcome was measured with different scales. Dichotomous variables were analyzed using the Mantel-Haenszel method in a random effects model. These variables were reported as risk ratios with 95% confidence intervals.

Quality assessment and evidence report formulation. We exported RevMan analyses into GRADEpro software to formulate a GRADE summary of findings table for each PICO question. The quality of evidence, such as the confidence in the effect estimates for each outcome, was evaluated based on GRADE quality assessment criteria. Two independent reviewers (RRB, MCS) performed this GRADE quality assessment in duplicate and discordance was resolved by consensus. This included the risk of bias in included trials, the likelihood of publication bias, inconsistency between trial results, indirectness of the evidence (e.g., differences between populations, interventions, or outcomes of interest in the group to whom the recommendation applies versus those who were included in the studies referenced), and imprecision (wide confidence intervals, usually due to a small number of patients or events, or those situations where clinical decision-making would differ at the extremes of the confidence interval).

The GRADE method distinguishes 4 levels of quality of evidence based on the degree of confidence that the pooled effect estimate lies close to the true effect. Thus, the quality of evidence for each outcome could be rated as high, moderate, low, or very low. The overall evidence quality grade was the lowest quality rating among the individual outcomes deemed

	Strong recommendation	*Conditional recommendation*
Patients	**Most people in your situation would want the recommended course of action and only a small proportion would not**	*The majority of people in your situation would want the recommended course of action, but many would not**
Clinicians	**Most patients should receive the recommended course of action**	*Be prepared to help patients to make a decision that is consistent with their own values*
Policy makers	**The recommendation can be adapted as a policy in most situations**	*There is a need for substantial debate and involvement of stakeholders*

Figure 1. Implications of strong and conditional GRADE (Grading of Recommendations Assessment, Development, and Evaluation) methodology recommendations (154). * = majority means >50% of the people.

critical for the comparison between interventions (14). In the absence of any data, the level of evidence was rated as very low, because it was based on clinical experience only.

We compiled the resulting summary of findings tables in an evidence report (see Supplementary Appendix 1, http://onlinelibrary.wiley.com/doi/10.1002/acr.22783/abstract) that was accompanied by a qualitative summary of the evidence for each PICO question. The Content Panel reviewed the drafted evidence report and revised the report to address evidence gaps prior to presentation to the Voting Panel. We referred to other society/organization guidelines for topics that do not exclusively relate to rheumatologic care, such as liver disease (American Association for the Study of Liver Diseases [AASLD]) and TB screening and immunization (Centers for Disease Control and Prevention [CDC]).

Moving from evidence to recommendations. Each recommendation was made based on a consideration of the balance of relative benefits and harms of the treatment options under consideration, the quality of the evidence (i.e., confidence in the effect estimates), and patients' values and preferences, as per GRADE methodology.

A recommendation could be either in favor of or against the proposed intervention and either strong or conditional. According to GRADE, a recommendation is categorized as strong if the panel is very confident that the benefits of an intervention far outweigh the harms (or vice versa) (7–9) (Figure 1). A conditional recommendation denotes uncertainty over the balance of benefits and harms, such as when the evidence quality is low or very low, or when patient preferences or costs are expected to impact the decision. Thus, conditional recommendations refer to decisions where incorporation of patient preferences is an essential element of decision making.

Consensus building. The Voting Panel received the evidence report for review before it met to discuss and decide on the final recommendations. For each PICO question, the Voting Panel heard an oral summary of the evidence and provided votes on the direction and strength of the related recommendation during a face-to-face meeting held on October 5–6, 2014, and subsequent conference calls and e-mails. The voting process was anonymous and conducted using Poll Everywhere software (available at www.polleverywhere.com). We used the 70% consensus threshold, which has been used previously in other similar processes (15) and in previous ACR guidelines (5,6). If 70% consensus was not achieved during an initial vote, the panel members held additional discussions before voting again. In some instances (specifically, DMARD monotherapy failure in early and established RA, hepatitis B, hepatitis C, and previously treated/untreated solid organ cancer), the Voting Panel decided, based on its review of the evidence and its round 1 votes, to combine certain treatment options. They then voted on a new recommendation statement that covered a group of treatment options instead of considering each question separately. In addition, the Voting Panel dropped a number of PICO questions because the clinical scenario was uncommon, irrelevant, or redundant (see Supplementary Appendix 4 available on the *Arthritis Care & Research* web site at http://onlinelibrary.wiley.com/doi/10.1002/acr.22783/abstract).

The GRADE methodology contributed a great deal of transparency to the voting process. For example, all of the evidence tables contained detailed descriptions of the criteria upon which the evidence quality was rated (such as estimates of risk of bias or indirectness). As allowed for in GRADE, in some instances, the Voting Panel chose to provide a recommendation in disagreement with the expected strength based on the overall evidence quality (i.e., a strong recommendation despite a low quality rating of evidence). In such cases, a written explanation was provided describing the reasons behind this decision.

Final review and approval of the manuscript by the ACR. In addition to journal peer review, the manuscript was reviewed by the ACR Guideline Subcommittee, ACR Quality of Care Committee, and the ACR Board of Directors, a process that involved over 40 reviewers (details available at www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines/Rheumatoid-Arthritis). These ACR oversight groups did not mandate that certain recommendations be made within the guideline, but rather, these ACR committees served as peer reviewers.

RESULTS/RECOMMENDATIONS

An abbreviated guideline summary of recommendations for patients with early RA, established RA, and high-risk comorbidities is available (see Executive Summary, Supplementary Appendix 5, available on the *Arthritis*

Table 2. Instruments to measure rheumatoid arthritis disease activity and to define remission*

Instrument (reference)	Thresholds of disease activity
Patient Activity Scale (PAS) or PASII (range 0–10) (149)	Remission: 0–0.25 Low activity: >0.25–3.7 Moderate activity: >3.7 to <8.0 High activity: ≥8.0
Routine Assessment of Patient Index Data 3 (RAPID3) (range 0–10) (155)	Remission: 0–1.0 Low activity: >1.0–2.0 Moderate activity: >2.0–4.0 High activity: >4.0–10
Clinical Disease Activity Index (CDAI) (range 0–76.0) (156)	Remission: ≤2.8 Low activity: >2.8–10.0 Moderate activity: >10.0–22.0 High activity: >22
Disease Activity Score (DAS) 28 erythrocyte sedimentation rate (ESR) (range 0–9.4) (157)	Remission: <2.6 Low activity: ≥2.6 to <3.2 Moderate activity: ≥3.2 to ≤5.1 High activity: >5.1
Simplified Disease Activity Index (SDAI) (range 0–86.0) (158)	Remission: ≤3.3 Low activity: >3.3 to ≤11.0 Moderate activity: >11.0 to ≤26 High activity: >26

* These 6 measures were endorsed by the American College of Rheumatology in 2012 (16). Other measures are now available to clinicians, but they were not included in this guideline because it was beyond the scope of this review. Adapted from ref. 16.

Care & Research web site at http://onlinelibrary.wiley.com/doi/10.1002/acr.22783/abstract).

How to interpret the recommendations

1. Strong recommendations are highlighted in green and bolded, and conditional recommendations are highlighted in yellow and italicized in the figures (Figure 1). A strong recommendation means that the panel was confident that the desirable effects of following the recommendation outweigh the undesirable effects (or vice versa), so the course of action would apply to most patients, and only a small proportion would not want to follow the recommendation. A conditional recommendation means that the desirable effects of following the recommendation probably outweigh the undesirable effects, so the course of action would apply to the majority of the patients, but some may not want to follow the recommendation. Because of this, conditional recommendations are preference sensitive and always warrant a shared decision-making approach.
2. In general, treatment choices are listed in the same order throughout the document (traditional DMARDs, TNFi, non-TNF, tofacitinib), and then alphabetically within each category. When more than one treatment is included as an option, the order does not imply any hierarchy, i.e., each of the treatment options (A or B or C) is recommended equally.

   For each recommendation, details regarding the supportive evidence or conditions (for conditional recommendations, but sometimes also for strong recommendations) are summarized in a section titled "Reasoning underlying the recommendations . . ." For example, conditions that the panel considered included comorbidities, patient perception of burden of taking medications, side-effect profile, and cost. Additional details including PICO questions and the GRADE evidence tables are available in Supplementary Appendix 1, http://onlinelibrary.wiley.com/doi/10.1002/acr.22783/abstract).
3. The Voting Panel members agreed to key principles and provisos, key terms, and descriptions prior to voting on the 2015 ACR RA treatment recommendations. These are explicitly stated in Table 1 and apply to the entire guideline. RA disease activity was defined as low, moderate, or high, as previously described (16) (Table 2).

Recommendations for the treatment of patients with early RA

Recommendations for treatment of early RA (disease duration <6 months) patients are provided in Figures 2 and 3. An executive summary of these recommendations is available in Supplementary Appendix 5, http://onlinelibrary.wiley.com/doi/10.1002/acr.22783/abstract.

Reasoning underlying the recommendations for the treatment of early RA. To achieve the above recommendations (Figure 2), the panel discussed several different PICO questions for early RA. The reasoning underlying the recommendations is described below.

PICO A.1. Despite the low quality evidence, the recommendation is **strong** because the Voting Panel concluded that the improved outcomes experienced by patients with established RA using a tar-

Recommendations for patients with symptomatic Early RA	Level of Evidence (evidence reviewed)
1. Regardless of disease activity level, use a treat-to-target strategy rather than a non-targeted approach (PICO A.1).	**Low (17)**
2. If the disease activity is low, in patients who have never taken a DMARD: **• use DMARD monotherapy (MTX preferred) over double therapy (PICO A.2).** **• use DMARD monotherapy (MTX preferred) over triple therapy (PICO A.3).**	**Low (18-21)** **Low (22-25)**
3. If the disease activity is moderate or high, in patients who have never taken a DMARD: *• use DMARD monotherapy over double therapy (PICO A.4).* *• use DMARD monotherapy over triple therapy (PICO A.5).*	*Moderate (18,20,21)* *High (22-25)*
4. If disease activity remains moderate or high despite DMARD monotherapy (with or without glucocorticoids), use combination DMARDs or a TNFi or a non-TNF biologic (all choices with or without MTX, in no particular order of preference), rather than continuing DMARD monotherapy alone (PICO A.7).	**Low (26-28)**
5. If disease activity remains moderate or high despite DMARDs: *• use a TNFi monotherapy over tofacitinib monotherapy (PICO A.8).* *• use a TNFi + MTX over tofacitinib + MTX (PICO A.9).*	*Low (29)* *Low (30)*
6. If disease activity remains moderate or high despite DMARD (PICO A.6) or biologic therapies (PICO A.12), add low-dose glucocorticoids.	*Moderate (31-37)* *Low (31-37)*
7. If disease flares, add short-term glucocorticoids at the lowest possible dose and for the shortest possible duration (PICO A.10, A.11).	*Very low (38-43)*

Figure 2. Summary of 2015 American College of Rheumatology recommendations for the treatment of Early rheumatoid arthritis (RA). Green and bolded = strong recommendation. A strong recommendation means that the panel was confident that the desirable effects of following the recommendation outweigh the undesirable effects (or vice versa), so the course of action would apply to most patients, and only a small proportion would not want to follow the recommendation. Yellow and italicized = conditional recommendation: The desirable effects of following the recommendation probably outweigh the undesirable effects, so the course of action would apply to the majority of the patients, but some may not want to follow the recommendation. Because of this, conditional recommendations are preference sensitive and always warrant a shared decision-making approach. A treatment recommendation favoring one medication over another means that the preferred medication would be the recommended first option and the nonpreferred medication may be the second option. Favoring one medication over the other does not imply that the nonfavored medication is contraindicated for use; it is still an option. Therapies are listed alphabetically; azathioprine, gold, and cyclosporine were considered but not included. Disease-modifying antirheumatic drugs (DMARDs) include hydroxychloroquine, leflunomide, methotrexate (MTX), and sulfasalazine. PICO = population, intervention, comparator, and outcomes; TNFi = tumor necrosis factor inhibitor. For definitions and descriptions, see Table 1.

geted approach should be generalizable to those with early RA (Figure 2).

PICOs A.2 and A.3. Despite the low quality evidence, the recommendation is **strong** because 1) there is no evidence in favor of triple therapy in this setting, 2) DMARD monotherapy is generally more acceptable (i.e., easier to take, less cost to the patient) to early RA patients with low disease activity than DMARD combination regimens, and 3) DMARD monotherapy is generally better tolerated than combination DMARD therapy. The panel also voted that methotrexate (MTX) should be the preferred initial DMARD for most early RA patients.

PICOs A.4 and A.5. The recommendation is *conditional* because 1) the evidence is of low quality and the evidence for differences in side effects is imprecise, 2) there is little difference in the benefit of double DMARD therapy over monotherapy, and 3) triple therapy might be preferred by some patients who desire a more rapid short-term benefit (e.g., earlier resumption of work activities) and are willing to assume potential added risk.

PICOs A.6 and A.12. The recommendation is *conditional* because 1) the evidence is of low quality, and 2) although glucocorticoid therapy is effective as a short-term (i.e., less than 3 months) therapy to "bridge" patients until realizing the benefits of DMARDs, this decision must be balanced by the lack of long-term glucocorticoid safety studies. The risk/benefit ratio of glucocorticoid therapy is favorable as long as the dose is low and the duration of therapy is short.

PICO A.7. The recommendation is **strong** despite the low quality of evidence because, for a patient failing DMARD monotherapy, clinical experience and indirect evidence support the benefits of adding these treatment options, and recommending no additional treatment is not an option. When deciding which therapy to use, considerations may include cost, comorbidities, burden of taking medications (i.e., 1 versus multiple, oral versus other routes) and side-effect profile. The panel also voted that biologic therapy should

Figure 3. 2015 American College of Rheumatology recommendations for the treatment of Early rheumatoid arthritis (RA), defined as disease duration <6 months. * = consider adding low-dose glucocorticoids (≤10 mg/day of prednisone or equivalent) in patients with moderate or high RA disease activity when starting disease-modifying antirheumatic drugs (DMARDs) and in patients with DMARD failure or biologic failure. † = also consider using short-term glucocorticoids (defined as <3 months treatment) for RA disease flares. Glucocorticoids should be used at the lowest possible dose and for the shortest possible duration to provide the best benefit-risk ratio for the patient. # = treatment target should ideally be low disease activity or remission. For the level of evidence supporting each recommendation, see the related section in the Results. This figure is derived from recommendations based on PICO (population, intervention, comparator, and outcomes) questions A.1 to A.12. For definitions of disease activity (categorized as low, moderate, or high) and descriptions, see Tables 1 and 2. MTX = methotrexate.

be used in combination with MTX, when possible, due to superior efficacy of this combination over biologic monotherapy.

PICOs A.8 and A.9. The recommendation is *conditional* because 1) the evidence is low quality, and 2) there are potential longer-term safety concerns related to tofacitinib that need more study, partly related to the shorter experience using tofacitinib.

PICOs A.10 and A.11. The recommendation is *conditional* because the evidence is of low quality because it is indirect, and the risk/benefit ratio of glucocorticoid therapy is favorable as long as the dose is low and duration of therapy is short.

Recommendations for the treatment of patients with established RA

Recommendations for treatment of established RA patients (disease duration ≥6 months), including tapering therapy, are provided in Figures 4 and 5. An executive summary of these recommendations is available in Supplementary Appendix 5, http://onlinelibrary.wiley.com/doi/10.1002/acr.22783/abstract.

Reasoning underlying the recommendations for the treatment of established RA

PICO B.1. The recommendation is **strong** because, based on moderate quality evidence, the panel concluded that the benefits far outweigh the risks for patients with established RA treated with a targeted approach compared to a non-targeted approach (Figure 4).

PICO B.2. The recommendation is **strong** despite the low quality of evidence because DMARD monotherapy is available as a less costly first-line therapy that has an extensive safety record with well-documented clinical efficacy, a large body of clinical experience, and familiarity among rheumatologists. The panel also voted that MTX should be the preferred initial DMARD for most patients with established RA who have never taken a DMARD.

PICO B.3. The recommendation is *conditional* despite the published positive tofacitinib efficacy data because the balance of benefit (tofacitinib slightly more efficacious), risk (long-term safety of tofacitinib is currently not well-known versus the well-known long-term safety of MTX), and cost considerations (MTX is less expensive than tofacitinib), favored MTX overall.

PICO B.4. The recommendation is *conditional* because the evidence is of low quality. The evidence supporting an incremental benefit for double DMARD therapy over DMARD monotherapy is indirect, and the evidence for differences in side effects is imprecise.

PICO B.5. The recommendation is **strong** despite moderate to very low quality of evidence because for a patient failing DMARD monotherapy, clinical experience and indirect evidence support the benefits of adding these treatment options, and recommending no treatment is not an option. The panel also voted that biologic therapy should be used in combination with MTX, when possible, due to superior efficacy of this combination over biologic monotherapy.

PICO B.6. The recommendation is **strong** because, compared to TNFi monotherapy, TNFi therapy has superior efficacy when used in combination with MTX, based on high quality evidence.

PICOs B.12 and B.14. The recommendation is *conditional* because 1) there is evidence for rituximab's efficacy in patients who have already received TNFi therapy, and for tocilizumab's superiority over a TNFi in patients already receiving MTX/DMARDs, and 2) there is evidence for efficacy of tocilizumab monotherapy.

PICOs B.13 and B.15. The recommendation is *conditional* because 1) the evidence is of very low quality, and 2) there is not enough difference in efficacy between non-TNF biologics and tofacitinib to outweigh the long-term safety data and the amount of experience associated with non-TNF biologics.

PICOs B.16 and B.17. The recommendation is *conditional* because 1) the evidence is of very low quality, 2) non-TNF biologics have longer-term safety data compared to tofacitinib, 3) there is greater long-term clinical experience with non-TNF biologics compared to tofacitinib, 4) there is not enough difference in efficacy between non-TNF biologics and tofacitinib to outweigh the longer-term safety data and greater amount of experience with non-TNF biologics, and 5) the fact that other non-TNF biologics with different mechanisms of action may be efficacious and worth trying.

PICOs B.8, B.9, B.10, and B.11. The recommendation is *conditional* because 1) the evidence is of very low quality, and 2) there is limited evidence, especially for the long-term safety data for tofacitinib.

PICOs B.23 and B.24. The recommendation is *conditional* because 1) the evidence is of very low quality, 2) improvement in outcomes as measured by the Health Assessment Questionnaire is numerically higher for patients randomized to tofacitinib compared to TNFi in an RCT; however, long-term safety data for tofacitinib are not yet available, and 3) some patients may prefer an oral formulation over an injection.

PICOs B.21 and B.22. The recommendation is *conditional* for the same reasons as cited above for PICOs B.16 and B.17 (except reason #2).

PICOs B.19 and B.20. The recommendation is *conditional* for the same reasons as cited above for PICOs B.23 and B.24.

Recommendations for patients with Established RA[1]	Level of Evidence (evidence reviewed)
1. Regardless of disease activity level, use a treat-to-target strategy rather than a non-targeted approach (PICO B.1).	**Moderate (44-46)**
2. If the disease activity is low, in patients who have never taken a DMARD, use DMARD monotherapy (MTX preferred) over a TNFi (PICO B.2).	**Low (47,48)**
3. *If the disease activity is moderate or high in patients who have never taken a DMARD:* • *use DMARD monotherapy (MTX preferred) over tofacitinib (PICO B.3).* • *use DMARD monotherapy (MTX preferred) over combination DMARD therapy (PICO B.4).*	*High (49)* *Moderate (18,20-25)*
4. **If disease activity remains moderate or high despite DMARD monotherapy, use combination traditional DMARDs *or* add a TNFi *or* a non-TNF biologic *or* tofacitinib (all choices with or without MTX, in no particular order of preference), rather than continuing DMARD monotherapy alone (PICO B.5).**	**Moderate to Very low (23,26,29,30,47,48,50-59)**
5. If disease activity remains moderate or high despite TNFi therapy in patients who are currently not on DMARDs, add one or two DMARDs to TNFi therapy rather than continuing TNFi therapy alone (PICO B.6).	**High (60-65)**
6. *If disease activity remains moderate or high despite use of a single TNFi:* • *use a non-TNF biologic, with or without MTX, over another TNFi with or without MTX (PICO B.12 and B.14).* • *use a non-TNF biologic, with or without MTX, over tofacitinib with or without MTX (PICO B.13 and B.15).*	*Low to Very low (66-72)* *Very low*[4]
7. *If disease activity remains moderate or high despite use of a single non-TNF biologic, use another non-TNF biologic, with or without MTX, over tofacitinib, with or without MTX (PICO B.16 and B.17).*	*Very low*[4]
8. *If disease activity remains moderate or high despite use of multiple (2+) sequential TNFi therapies, first use a non-TNF biologic, with or without MTX, over another TNFi or tofacitinib (with or without MTX) (PICO B.8, B.9, B.10, B.11).*	*Very low (73-75)*
9. *If the disease activity still remains moderate or high despite the use of multiple TNFi therapies, use tofacitinib, with or without MTX, over another TNFi, with or without MTX, if use of a non-TNF biologic is not an option (PICO B.23 and B.24).*	*Low (29,30)*
10. *If disease activity remains moderate or high despite use of at least one TNFi and at least one non-TNF-biologic:* • *first use another non-TNF biologic, with or without MTX, over tofacitinib (PICO B.21 and B.22).* • *If disease activity remains moderate or high, use tofacitinib, with or without MTX, over another TNFi (PICO B.19 and B.20).*	*Very low (29,30)* *Very low (29)*
11. *If disease activity remains moderate or high despite use of DMARD, TNFi, or non-TNF biologic therapy, add short-term, low dose glucocorticoid therapy (PICO B.26 and B.27).*	*High to Moderate (33,41,76,77)*
12. *If disease flares in patients on DMARD, TNFi, or non-TNF biologic therapy, add short-term glucocorticoids at the lowest possible dose and the shortest possible duration (PICO B.28 and B.29).*	*Very low (40-43)*
13. *If the patient is in remission:* • *taper DMARD therapy (PICO B.31)*[2]**.** • *taper TNFi, non-TNF biologic, or tofacitinib (PICO B.33, B.35, B.37) (please also see #15).*	*Low*[3] *(78)* *Moderate to Very low*[3] *(79,80)*
14. **If disease activity is low:** • **continue DMARD therapy (PICO B.30).** • **continue TNFi, non-TNF biologic or tofacitinib rather than discontinuing respective medication (PICO B.32, B.34 and B.36).**	**Moderate (78)** **High to Very low (79,80)**
15. **If the patient's disease is in remission, do not discontinue all RA therapies (PICO B.38).**	**Very low**[4]

Figure 4. Summary of 2015 American College of Rheumatology (ACR) recommendations for the treatment of Established rheumatoid arthritis (RA). Green and bolded = strong recommendation. A strong recommendation means that the panel was confident that the desirable effects of following the recommendation outweigh the undesirable effects (or vice versa), so the course of action would apply to most patients, and only a small proportion would not want to follow the recommendation. Yellow and italicized = conditional recommendation: The desirable effects of following the recommendation probably outweigh the undesirable effects, so the course of action would apply to the majority of the patients, but some may not want to follow the recommendation. Because of this, conditional recommendations are preference sensitive and always warrant a shared decision-making approach. A treatment recommendation favoring one medication over another means that the preferred medication would be the recommended first option and the nonpreferred medication may be the second option. Favoring one medication over the other does not imply that the nonfavored medication is contraindicated for use; it is still an option. Therapies are listed alphabetically; azathioprine, gold, and cyclosporine were considered but not included. Disease-modifying antirheumatic drugs (DMARDs) include hydroxychloroquine, leflunomide, methotrexate (MTX), and sulfasalazine. 1 = definition of established RA is based on the 1987 ACR RA classification criteria (81), since the 2010 ACR/European League Against Rheumatism RA classification allows classification of a much earlier disease state (82). 2 = tapering means scaling back therapy (reducing dose or dosing frequency), not discontinuing it. Tapering should be considered an option and not be mandated. If done, tapering must be conducted slowly and carefully, watching for increased disease activity and flares. Even for patients whose RA is in remission, there is some risk of flare when tapering. 3 = evidence is rated low quality or moderate to very low quality because some evidence reviewed for this recommendation was indirect and included studies with discontinuation rather than tapering of therapy or since studies involved patients achieving low disease activity rather than remission. 4 = no studies were available, leading to very low quality evidence, and the recommendation was based on clinical experience. PICO = population, intervention, comparator, and outcomes; TNFi = tumor necrosis factor inhibitor. For definitions and descriptions, see Table 1.

Figure 5. 2015 American College of Rheumatology (ACR) recommendations for the treatment of Established rheumatoid arthritis (RA), defined as disease duration ≥6 months, or meeting the 1987 ACR classification criteria (81). Due to complexity of management of established RA, not all clinical situations and choices could be depicted in this flow chart, and therefore we show the key recommendations. For a complete list of recommendations, please refer to the Results. * = consider adding low-dose glucocorticoids (≤10 mg/day of prednisone or equivalent) in patients with moderate or high RA disease activity when starting traditional disease-modifying antirheumatic drugs (DMARDs) and in patients with DMARD failure or biologic failure. † = also consider using short-term glucocorticoids (defined as <3 months treatment) for RA disease flares. Glucocorticoids should be used at the lowest possible dose and for the shortest possible duration to provide the best benefit-risk ratio for the patient. # = treatment target should ideally be low disease activity or remission. ** = tapering denotes scaling back therapy (reducing dose or dosing frequency), not discontinuing it and if done, must be conducted slowly and carefully. For the level of evidence supporting each recommendation, see the related section in the Results. This figure is derived from recommendations based on PICO (population, intervention, comparator, and outcomes) questions B.1 to B.38. For definitions of disease activity (categorized as low, moderate, or high) and descriptions, see Tables 1 and 2. MTX = methotrexate; TNFi = tumor-necrosis factor inhibitor.

Table 3. Recommendations for optimal followup laboratory monitoring intervals for complete blood count, liver transaminase levels, and serum creatinine levels for patients with rheumatoid arthritis receiving disease-modifying antirheumatic drugs*

	Monitoring interval based on duration of therapy‡		
Therapeutic agents†	**<3 months**	**3–6 months**	**>6 months**
Hydroxychloroquine	None after baseline§	None	None
Leflunomide	2–4 weeks	8–12 weeks	12 weeks
Methotrexate	2–4 weeks	8–12 weeks	12 weeks
Sulfasalazine	2–4 weeks	8–12 weeks	12 weeks

* More frequent monitoring is recommended within the first 3 months of therapy or after increasing the dose, and the outer bound of the monitoring interval is recommended beyond 6 months of therapy. Adapted from ref. 6.
† Listed alphabetically.
‡ The panel indicated that patients with comorbidities, abnormal laboratory results, and/or multiple therapies may require more frequent laboratory testing than what is generally recommended laboratory monitoring for disease-modifying antirheumatic drugs in the table.
§ See ref. 6 for baseline monitoring recommendations.

PICOs B.26 and B.27. The recommendation is *conditional* because the risk/benefit ratio of glucocorticoid therapy is favorable as long as the dose is low and duration of therapy is short.

PICOs B.28 and B.29. The recommendation is *conditional* because 1) the evidence is of very low quality, and 2) the risk/benefit ratio of glucocorticoid therapy is favorable as long as the dose is low and duration of therapy is short.

The panel also made several recommendations related to tapering therapy, with the following general caveats: 1) "Tapering" is defined as scaling back therapy 1 medication at a time (reducing dose or dosing frequency), 2) Patients' values and preferences should drive decisions related to tapering, 3) A comprehensive plan to monitor disease activity and address possible flares is implemented, and 4) Prior to tapering, RA patients, including those in sustained remission, are informed of the risk of flare.

PICOs B.31, B.33, B.35, and B.37. The recommendation is *conditional* because 1) the evidence is of low quality, 2) while tapering carries a risk of flare, minimizing therapy may decrease toxicity, and/or cost, and lowers the risk of treating patients unnecessarily.

PICOs B.30, B.32, B.34, and B.36. The recommendation is **strong** because based on clinical observations and experience only a small minority of patients with low disease activity (not remission) is able to successfully discontinue all RA therapy.

PICO B.38. The recommendation is **strong** despite very low quality of evidence because based on clinical experience, the risk of RA flare and the need for resumption of therapy are high, if all RA therapies are discontinued.

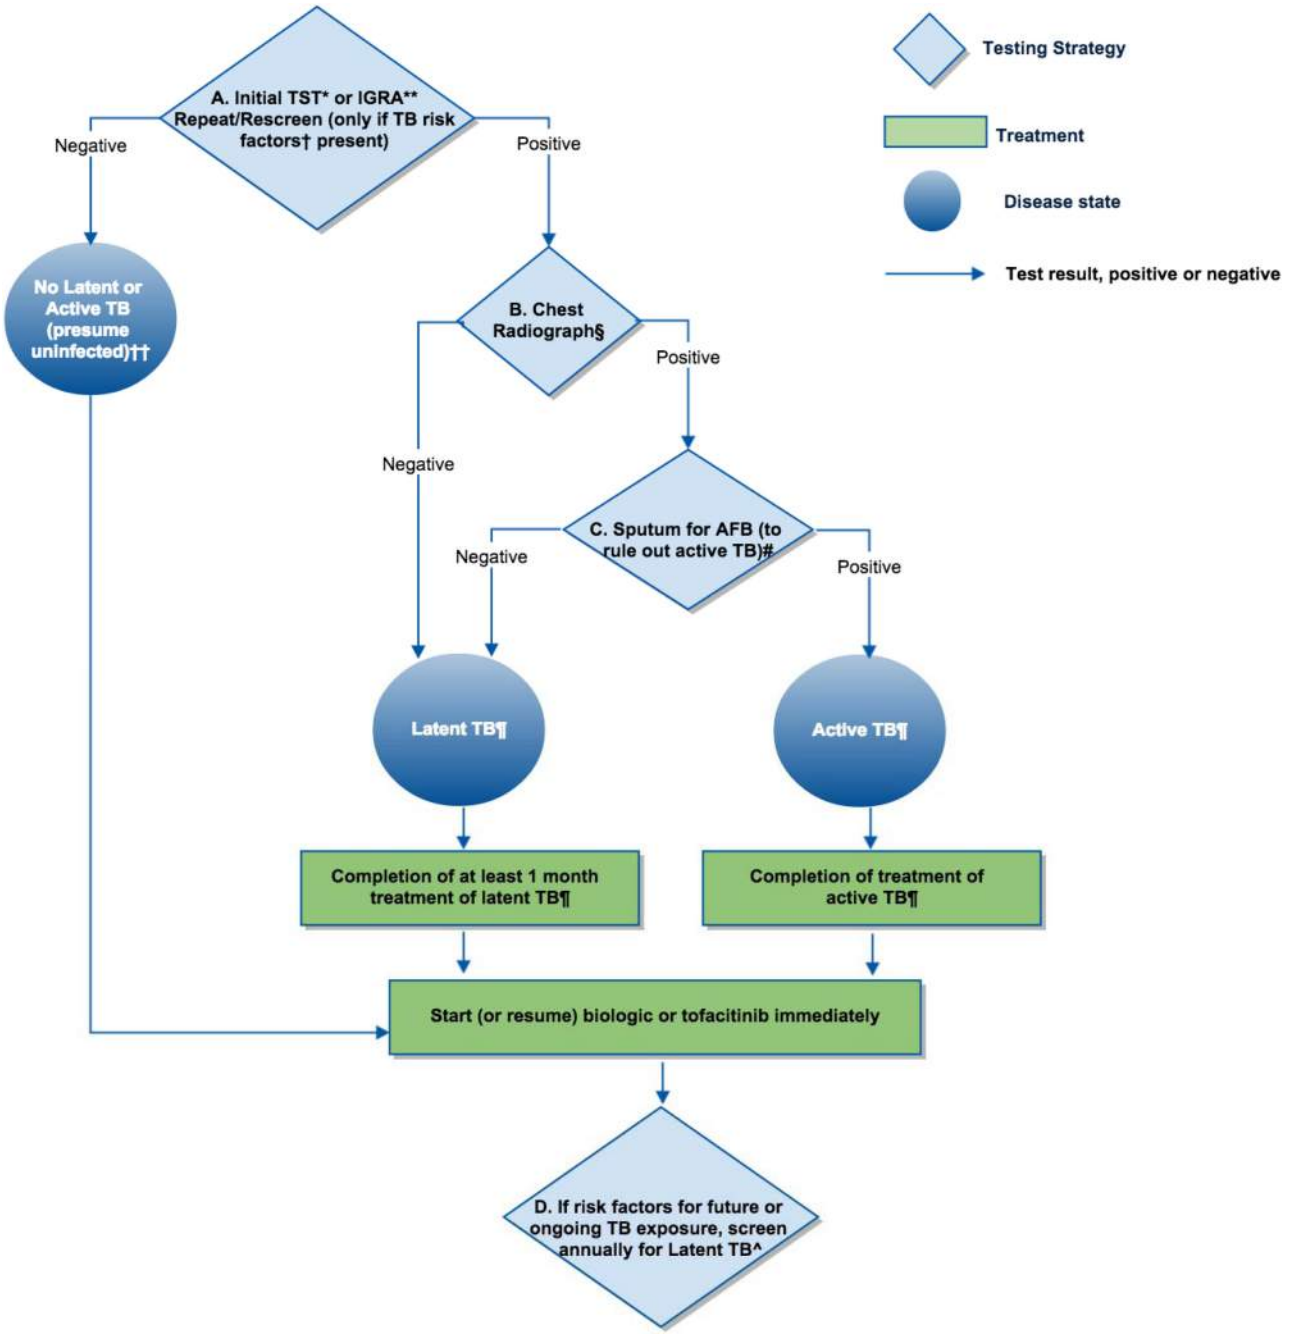
The Voting Panel also voted on 2 additional PICO questions (B.7 and B.18) to fill the remaining gaps in the treatment algorithm after the initial voting (Figure 5). Both compare therapy with no therapy. We followed the GRADE methodology and the same process for these PICO questions.

PICO B.7. If disease activity remains moderate or high despite the use of a single TNFi, the recommendation is *conditional* for using another TNFi rather than not using a TNFi. The recommendation is *conditional* because both evidence from TNFi studies and clinical experience support response to a second TNFi in a significant proportion of patients, especially in the presence of secondary failure (i.e., a TNFi worked initially and then stopped working). For additional recommendations related to this patient population, see PICOs B.12, B.15, B.23, and B.24.

PICO B.18. If disease activity remains moderate or high despite the use of multiple non-TNF biologics and the patient is TNFi-naive, the recommendation is *conditional* for using TNFi rather than not using TNFi. The recommendation is *conditional* because the evidence is of very low quality. Although there are no trials of patients with multiple non-TNF biologic failures, if non-TNF biologics have not been effective and TNFi therapy has not yet been given, then TNFi therapy should be tried, unless there are contraindications for its use.

Recommendations for laboratory monitoring for DMARDs and TB screening in patients receiving biologics or tofacitinib

The panel endorsed the recommendations previously published in the 2008 recommendations and in the 2012 update to be included in the 2015 recommendations (Table 3 and Figure 6). The panel indicated that in the absence of significant new knowledge, development of an alternate rec-



Testing Strategy

Completion of treatment of active TB¶
Start (or resume) biologic or tofacitinib immediately
D. If risk factors for future or ongoing TB exposure, screen annually for Latent TB^

Figure 6. Tuberculosis (TB) screening algorithm for biologics or tofacitinib (endorsed and modified from the 2012 American College of Rheumatology RA treatment recommendations). The Voting Panel reviewed and endorsed the 2012 TB screening algorithm with 1 change, that tofacitinib should be included alongside biologics. * = anergy panel testing is not recommended. ** = interferon-gamma release assay (IGRA) is preferred if patient has a history of BCG vaccination. † = risk factors for TB exposure are defined based on a publication from the US Centers for Disease Control and Prevention as: close contacts of persons known or suspected to have active TB, foreign-born persons from areas that have a high incidence of active TB (e.g., Africa, Asia, Eastern Europe, Latin America, and Russia), persons who visit areas with a high prevalence of active TB, especially if visits are frequent or prolonged, residents and employees of congregate settings whose clients are at increased risk for active TB (e.g., correctional facilities, long-term care facilities, and homeless shelters), health care workers who serve clients who are at increased risk for active TB, populations defined locally as having an increased incidence of latent *Mycobacterium tuberculosis* infection or active TB, possibly including medically underserved, low-income populations, or persons who abuse drugs or alcohol, and infants, children, and adolescents exposed to adults who are at increased risk for latent *M tuberculosis* infection or active tuberculosis (159,160). †† = if patient is immunosuppressed and false-negative results more likely, consider repeating screening test(s) with tuberculin skin test (TST) or IGRA. § = chest radiography may also be considered when clinically indicated in patients with risk factors, even with a negative result on repeat TST or IGRA. # = obtain respiratory (e.g., sputum, bronchoalveolar lavage) or other samples as clinically appropriate for acid-fast bacilli (AFB) smear and culture. Consider referral to TB specialist for further evaluation and treatment. ¶ = in a patient diagnosed as having latent or active TB, consider referral to a specialist for the recommended treatment. ^ = patients who test positive for TST or IGRA at baseline (pretreatment) often remain positive for these tests even after successful treatment of TB. These patients need monitoring for clinical signs and symptoms of recurrent TB disease, since repeating tests will not allow help in diagnosis of recurrent TB. The level of evidence supporting each recommendation for TB reactivation was derived from consensus opinion of experts, case studies, or standards of care. The level of evidence for initiation of biologics in patients being treated for latent TB infection was higher, with data derived from a single randomized trial or nonrandomized studies. Adapted from ref. 5.

ommendation was not warranted with one exception: the Voting Panel recommended that the same TB screening algorithm as described for biologics should be followed for patients receiving tofacitinib. For additional details (including baseline laboratory monitoring), please see the 2008 and 2012 guidelines (5,6).

Recommendations in RA patients with high-risk comorbidities

Recommendations are provided in Figure 7. An executive summary of these recommendations is available in Supplementary Appendix 5, http://onlinelibrary.wiley.com/doi/10.1002/acr.22783/abstract.

Congestive heart failure

PICOs C.1, C.2, C.3, C.4, C.5, and C.6. The recommendations are *conditional* because the evidence is of very low quality. The Voting Panel noted that there are no reports of exacerbation of heart failure using non-TNF biologics and the US Food and Drug Administration (FDA) warns against using TNFi in this population based on worsening of congestive heart failure with TNFi in the Adverse Event Reporting System database. A TNFi should only be used if there are no other reasonable options, and then, perhaps, only in compensated heart failure (83,84) (Figure 7).

Hepatitis B

To address hepatitis B, the AASLD practice guidelines were reviewed (85,86). These guidelines suggest that immunosuppressive therapy can be safely utilized when prophylactic antiviral therapy is prescribed concomitantly.

PICO D.1. The recommendation is **strong** despite very low evidence (85–92) because clinical experience supports the benefits of treating these RA patients with active disease, and an absence of additional harms, if patients are receiving concomitant effective antiviral treatment. The Voting Panel further specified that for a patient with natural immunity from prior exposure to hepatitis B (i.e., hepatitis B core antibody positive, normal liver function tests, and hepatitis B surface [HBs] antibody positive and HBs antigen negative), RA treatment should be the same as that of unexposed patients, as long as the patient's viral load is monitored regularly (117,118), conservatively, every 6–12 months. For patients with chronic hepatitis B who are untreated, referral for antiviral therapy is appropriate prior to immunosuppressive therapy (88,119–124). A recent review summarized this evidence (125).

Hepatitis C

PICO E.1. The recommendation is *conditional* because the evidence is of very low quality, i.e., indirect evidence from patient populations other than RA (92–103). The evidence suggests that these RA patients with hepatitis C virus (HCV) infection should *not* be treated differently than RA patients who do not have hepatitis C. The Voting Panel recommended that rheumatologists collaborate with gastroenterologists and/or hepatologists to monitor patients receiving antiviral therapy. This is important considering the recent availability of highly effective therapy for HCV, which might lead to a greater number of HCV patients being treated successfully.

PICO E.2. The recommendation is *conditional* because the evidence is of very low quality. For patients with HCV infection or exposure, the safety of biologic therapy was addressed indirectly by 2 RCTs and a variety of small observational studies including case series (92–103). Much of this research was not confined to individuals with RA. This very low-level evidence suggests that TNFi therapy can be safely administered in HCV-positive patients, if treatment with antiviral therapy is used. One small, long-term observational study of HCV-positive individuals receiving TNFi immunosuppression found that increased HCV activity was associated with the absence of concomitant antiviral therapy (93). In a small RCT of HCV-positive individuals with RA who did not require antiviral therapy, neither patients treated with MTX nor patients treated with TNFi therapy demonstrated significant change in viral load (98). The Voting Panel recommended that rheumatologists collaborate with gastroenterologists and/or hepatologists in recommending individualized treatment based on other comorbidities, reason(s) for not receiving HCV treatment, and the need to minimize immunosuppression, and consider using DMARDs other than MTX or leflunomide, such as sulfasalazine *or* hydroxychloroquine.

Malignancy

Previous melanoma and non-melanoma skin cancer. Separate PICO questions addressed melanoma and non-melanoma skin cancer, but the recommendations were similar, and therefore were combined.

PICOs F.1, F.2, F.3, and F.4. The recommendation is *conditional* because 1) the evidence is of very low quality, 2) due to potentially lower risk of recurrence of skin cancer with DMARDs versus other therapies based on clinical experience and 2 retrospective studies (104,105), and 3) a lack of data and knowledge about some of the mechanisms of action of biologics and tofacitinib, which may potentially contribute to an increased cancer risk. DMARDs were considered less immunosuppressive than biologics. The Voting Panel also stated that host factors may vary and may influence the risk of

High-risk condition	Recommendation	Level of Evidence (evidence reviewed)
Congestive heart failure[1]		
CHF	*Use combination DMARDs or non-TNF biologic or tofacitinib over TNFi (PICO C.1, C.2 and C.3).*	*Moderate to Very low (83,84)*
CHF worsening on current TNFi therapy	*Use combination DMARDs or non-TNF biologic or tofacitinib over another TNFi (PICO C.4, C.5 and C.6).*	*Very low[7]*
Hepatitis B[2]		
Active Hepatitis B infection and receiving/received effective antiviral treatment	**Same recommendations as in patients without this condition (PICO D.1).**	**Very low (85-92)**
Hepatitis C[2]		
Hepatitis C infection and receiving/received effective antiviral treatment	*Same recommendations as in patients without this condition (PICO E.1).*	*Very low (92-103)*
Hepatitis C infection and not receiving or requiring effective antiviral treatment	*Use DMARDs over TNFi (PICO E.2)[3].*	*Very low (92-103)*
Past history of treated or untreated malignancy[4]		
Previously treated or untreated skin cancer (non-melanoma or melanoma)	*Use DMARDs over biologics in melanoma (PICO F.1).* *Use DMARDs over tofacitinib in melanoma (PICO F.2).* *Use DMARDs over biologics in non-melanoma (PICO F.3).* *Use DMARDs over tofacitinib in non-melanoma (PICO F.4).*	*Very low (104-106)*
Previously treated lymphoproliferative disorder	**Use rituximab over TNFi (PICO G.1).**	**Very low (105,107)**
Previously treated lymphoproliferative disorder	*Use combination DMARD or abatacept or tocilizumab over TNFi* (PICO G.2, G.3 and G.4).	*Very low (105,107)*
Previously treated solid organ malignancy	*Same recommendations as in patients without this condition (PICO H.1).*	*Very low (105,108)*
Previous Serious Infection(s)[5]		
Previous Serious infection(s)	*Use combination DMARD over TNFi (PICO I.1)[5].* *Use abatacept over TNFi (PICO I.2)[6].*	*Very low (109-116)*

Figure 7. Summary of 2015 American College of Rheumatology recommendations for high-risk patients with established rheumatoid arthritis with moderate or high disease activity and congestive heart failure (CHF), hepatitis B or C, past history of malignancy, or serious infection(s). Green and bolded = strong recommendation. A strong recommendation means that the panel was confident that the desirable effects of following the recommendation outweigh the undesirable effects (or vice versa), so the course of action would apply to most patients, and only a small proportion would not want to follow the recommendation. Yellow and italicized = conditional recommendation. The desirable effects of following the recommendation probably outweigh the undesirable effects, so the course of action would apply to the majority of the patients, but some may not want to follow the recommendation. Because of this, conditional recommendations are preference sensitive and always warrant a shared decision-making approach. A treatment recommendation favoring one medication over another means that the preferred medication would be the recommended first option and the nonpreferred medication may be the second option. Favoring one medication over the other does not imply that the nonfavored medication is contraindicated for use; it is still an option. 1 = conditional recommendations supported by evidence level ranging from moderate level to no evidence, supported by clinical experience and the Food and Drug Administration safety warning with tumor necrosis factor inhibitors (TNFi). 2 = strong recommendations for Hepatitis B were largely based upon the recent American Association for the Study of Liver Diseases practice guidelines (85,86) and clinical experience; conditional recommendations for Hepatitis C were largely supported by very low level evidence based upon case series and clinical experience. 3 = consider using DMARDs other than methotrexate or leflunomide, such as sulfasalazine *or* hydroxychloroquine. 4 = conditional recommendations supported by level of evidence ranging from very low to no evidence, are largely based upon expert opinion and clinical experience. 5 = conditional recommendation was supported by very low level evidence. 6 = there was no consensus for making recommendations regarding the use of rituximab over TNFi or the use of tocilizumab over TNFi in this setting, due to indirect evidence (e.g., no comparison to TNFi or including patients with tuberculosis) and differences of opinion. In 1 study, compared to patients who restarted their previous TNFi following hospitalized infections, patients who switched to abatacept exhibited lower risk of subsequent hospitalized infections among the therapies examined. 7 = no studies were available, leading to very low quality evidence, and the recommendation was based on clinical experience. DMARDs = disease-modifying antirheumatic drugs; PICO = population, intervention, comparator, and outcomes.

Figure 8. 2015 American College of Rheumatology (ACR) recommendations update regarding the use of vaccines in patients with rheumatoid arthritis (RA) starting or currently receiving disease-modifying antirheumatic drugs (DMARDs) or biologics. ✓ = recommend vaccination when indicated (based on age and risk). Red indicates vaccinations not recommended. The panel endorsed all 2012 RA treatment recommendations for vaccination with 1 exception (see footnote 6), and re-voted only for certain immunization recommendations in patients receiving biologics. All recommendations were *conditional*, except that the panel strongly recommended (in green) using appropriately indicated killed/inactivated vaccines in patients with early or established RA who are currently receiving biologics. Evidence level was very low for recommendations based on population, intervention, comparator, and outcomes (PICOs) J.1, J.2, J.3, J.4, and J.5. Evidence level for the remaining recommendations that were endorsed from the 2012 ACR RA treatment guideline was similar (on a different scale). 1 = the Centers for Disease Control and Prevention (CDC) also recommends a one-time pneumococcal revaccination after 5 years for persons with chronic conditions such as RA. The CDC recommends pneumococcal conjugate vaccine (PCV13 or Prevnar 13) for all children younger than 5 years of age, all adults ≥65 years, and persons 6−64 years of age with certain medical conditions. Pneumovax is a 23-valent pneumococcal polysaccharide vaccine (PPSV23) that is currently recommended for use in all adults ≥65 years old and for persons who are ≥2 years old and at high risk for pneumococcal disease (e.g., those with sickle cell disease, HIV infection, or other immunocompromising conditions). PPSV23 is also recommended for use in adults 19−64 years of age who smoke cigarettes or who have asthma (http://www.cdc.gov/vaccines/vpd-vac/pneumo/default.htm?s_cid=cs_797). 2 = if hepatitis B risk factors are present (e.g., intravenous drug abuse, multiple sex partners in the previous 6 months, health care personnel). 3 = the panel conditionally recommended that in RA patients ages ≥50 years, the herpes zoster vaccine should be given before the patient receives biologic therapy or tofacitinib for their RA. 4 = response to certain killed vaccines may be reduced after rituximab therapy. 5 = the panel conditionally recommended giving the herpes zoster vaccine before the patient receives biologic therapy or tofacitinib for their RA in both early or established RA patients ages ≥50 years (PICO J.1). The panel also voted that after giving the herpes zoster vaccine, there should be a 2-week waiting period before starting biologics. 6 = the panel strongly recommended that in patients with early or established RA who are currently receiving biologics, appropriately indicated killed/inactivated vaccines should be used (PICOs J.4 and J.5). 7 = the panel conditionally recommended that in early or established RA patients who are currently receiving biologics, live attenuated vaccines such as the herpes zoster (shingles) vaccine should not be used (PICOs J.2 and J.3). TNFi = tumor necrosis factor inhibitor. For definitions and descriptions, see Table 1. Adapted from ref. 5.

recurrence of skin cancer. Even though biologics were not the first option, several Voting Panel members indicated that if the joint disease was moderately or highly active in the setting of a low-grade melanoma or non-melanoma skin cancer that had been previously treated, biologics would be an acceptable option with close skin surveillance in conjunction with a dermatologist.

It is important to note that although the panel voting on PICO F.3 (using a DMARD rather than a biologic for patients with a prior history of non-melanoma skin cancer) achieved the necessary 70% threshold for consensus, there was 1 Voting Panel member with a dissenting view that the risk difference between DMARDs and biologics in RA patients with a previously treated or untreated non-melanoma skin cancer may be insignificant, and 2 other Voting Panel members also shared some of these concerns but voted conditionally in favor of DMARDs.

Previous lymphoproliferative disorders

PICO G.1. The recommendation is **strong** despite very low quality evidence because rituximab is an approved treatment for some of these disorders and the best available clinical trial data suggest that there is a signal in clinical trials of induction and/or an increased risk of lymphoma in patients treated with TNFi (105,107).

PICOs G.2, G.3, and G.4. The recommendation is *conditional* because 1) the evidence is of very low quality (105,107), 2) there is a lack of evidence for combination DMARD therapy versus TNFi (PICO G.2), and 3) as described in PICO G.1, there is a possible increased risk of lymphoma associated with TNFi, but there is no evidence that abatacept or tocilizumab increases this risk (PICOs G.3 and G.4).

Previous solid organ cancer

PICO H.1. The recommendation is *conditional* because the evidence is of very low quality (105,108).

Serious infections

PICOs I.1 and I.2. The recommendation is *conditional* because 1) the evidence is of very low quality (indirect), as most trials excluded patient groups with a high risk of serious infections, and 2) rheumatologists have greater experience with DMARDs compared to TNFi in patients with previous serious infections. The recommendation regarding abatacept is conditional because the evidence is very low quality. In one study, compared to patients who restarted their previous TNFi following hospitalized infections, patients who switched to abatacept exhibited the lowest risk of subsequent hospitalized infection among the therapies examined (109).

Recommendations for use of vaccines in RA patients receiving DMARD and/or biologic therapy

Recommendations for use of vaccines in RA patients on DMARD and/or biologic therapy are provided in Figure 8.

PICO J.1. The recommendation is *conditional* because the evidence is of very low quality. The CDC has recommended the herpes zoster vaccine for people ages ≥60 years in the general population, but not for adults ages 50–59 years, even though the FDA approved the vaccine in adults ≥50 years. The CDC reconsidered the use of vaccination in people 50–59 years in 2013 and decided not to change its current recommendation for the general population, but did not vote (126). Our Voting Panel considered these recommendations and, because the immune systems of RA patients are compromised by the disease or by medications, the panel agreed that patients with RA ages ≥50 years should be vaccinated before receiving biologic or tofacitinib therapy because the benefits of doing so likely outweigh the risks in this population.

PICOs J.2 and J.3. The recommendation is *conditional* because 1) the evidence is of very low quality (127,128), and 2) there is a safety warning about the use of live vaccines in patients receiving biologics (127,128) (see Zostavax packet insert available at https://www.merck.com/product/usa/pi_circulars/z/zostavax/zostavax_pi2.pdf).

PICOs J.4 and J.5. The recommendation is **strong** despite very low quality of evidence (129–135) because of the documented benefit of killed vaccines in adults and no significant concerns of harm in RA patients receiving biologics, as per the general guidance from the CDC. Clinicians should consult the CDC recommendations for killed vaccines (136–140). Responses to some killed vaccines may be reduced after rituximab therapy (141) and possibly after MTX therapy. Whenever possible, vaccines should be given *prior to* receiving therapy.

In addition to these recommendations, the Voting Panel endorsed the vaccination recommendations made in 2012, with the 1 exception mentioned above, i.e., responses to certain killed vaccines may be reduced after rituximab therapy (141) (Figure 8).

DISCUSSION

The 2015 ACR RA treatment guideline addresses the use of DMARDs, biologics, tofacitinib, and glucocorticoids in early and established RA and the use of various treatment approaches in frequently encountered clinical scenarios, including treat-to-target, switching between therapies, tapering of therapy, the use of biologics and DMARDs in high-risk RA patients, vaccination in patients with RA receiving DMARDs or biologics, TB screening with biologics or tofacitinib, and laboratory monitoring with DMARDs. The recommendations aim to provide guidance for clinicians and patients in an era of rapid advances in the treatment of RA. These recommendations were developed using scientific evidence, a rigorous, well-defined guideline development methodology, and a group consensus process. Compared to earlier treatment guidelines, there were several differences in the development of the 2015 RA treatment recommendations.

First, we used the GRADE methodology because it provides an internationally accepted systematic approach to guideline development. PICO questions were developed with the intended patient populations and outcomes explicitly listed. Before beginning the evidence synthesis, we posted the PICO questions online and solicited feedback and comments from the ACR membership. We also noted dissenting views. An example is the dissenting view related to the conditional recommendation for DMARDs over biologics for RA patients with previously treated or untreated non-melanoma skin cancer. Even though the panel reached consensus with 90% voting in favor, 1 panel member had a dissenting opinion and voted for biologic therapy over DMARD therapy in this situation. It should be noted that melanoma and non-melanoma were considered and voted on separately by the panel but that the final recommendations were similar for both situations and, therefore, are presented as a single recommendation.

Unlike previous ACR RA guidelines, the panel decided to base these new recommendations only on patients' disease activity level rather than including both disease activity and prognosis. The justification for this approach was that adding another variable (prognosis) to the PICO questions would have made the project much less feasible. Also, the Content Panel and the Voting Panel agreed that disease prognosis was largely captured in the concept of disease activity and that information regarding prognosis was unlikely to further contribute to decision-making.

Recommendations related to immunization and treatment in patients with RA and coexistent viral hepatitis B or C were informed primarily by the CDC (138) and the AASLD guidelines (85,86), respectively, and require fur-

ther explanation. The panel made a *conditional* recommendation to use herpes zoster immunization at age 50 and older prior to starting biologics, considering the higher infection risk due to RA and its treatments. This is consonant with the FDA approval for the use of herpes zoster vaccine in adults ages ≥50 years, and despite current CDC recommendations to use the vaccine in the general population (i.e., not RA patients) at ages ≥60 years. The panel also stated that as long as RA patients with viral hepatitis were started on the appropriate antiviral treatments for hepatitis B and C prior to initiation of RA therapy, they could be treated similarly to RA patients without these chronic viral infections. Case reports, case series, and small observational studies of RA patients with hepatitis B or C who have been treated with medications for RA provided additional supportive evidence. However, the data are limited in these clinical settings, and close monitoring of such patients and consultation with the appropriate specialists is advised.

The Voting Panel strongly recommended the use of combination traditional DMARDs *or* addition of a TNFi *or* a non-TNF biologic *or* tofacitinib for patients with established RA with moderate or high disease activity despite DMARD monotherapy. After carefully considering the evidence, the panel concluded that the limited direct comparative evidence for these therapies in this clinical situation precluded recommending a ranking of these treatment options.

Due to rapidly evolving knowledge for the treatment of RA, some recommendations may be outdated by the time they are published due to the emergence of new evidence. Examples include new data on tapering and discontinuation of therapies in early RA (142) and treat-to-target (143). The short half-life of treatment recommendations is also related to the rigorous and time-consuming process of guideline development used by the ACR, which complies with guidance from the National Academy of Medicine (formerly the Institute of Medicine) and the Council for Medical Subspecialty Societies. Additional time is also required for review and endorsement of each guideline document by ACR committees, journal reviewers and editors, and the ACR Board of Directors. However, the ACR regularly updates RA guidelines and strives to shorten the time between the end of the literature review and the publication of guidelines, to make them as relevant and current as possible.

The panel provided "conditions" when making a conditional recommendation. The listed conditions were not necessarily exhaustive for each recommendation, but included those factors that were most important in determining the final panel vote. This process ensured that conditions were a direct reflection of the Voting Panel members' discussion and agreements. Although we used 70% as the agreement threshold, for 80% of the recommendations there was 90% consensus (of which 50% of the recommendations had 100% consensus). We noted that 77% of the recommendations were conditional and the remaining 23% were strong. This was partially due to the lack of evidence for common clinical situations, and our a priori decision that PICO questions should be based on what is important for a clinician and patient to know, not based on the presence or absence of the highest level of evidence. This indicates that more evidence is needed to derive strong RA recommendations in the future. A number of recommendations were strong despite low quality evidence, which is allowed according to GRADE methodology, and the Voting Panel provided justification for these recommendations.

Several important aspects of RA care were not addressed due to resource limitations, including the use of nonpharmacologic interventions (e.g., physical therapy, occupational therapy, assistive devices), use of biologics and DMARDs in other less-common conditions (e.g., new diagnosis of cancer, family history of cancer or multiple sclerosis, new diagnosis of hepatitis while receiving successful RA therapy). The Voting Panel considered the dosing issues related to glucocorticoids and MTX and believed strongly that it was not within its charge to mandate dosing. Recommendations for individual medications (e.g., various DMARDs, TNFi, non-TNF biologics) were not made, since an a priori decision was made to examine these as categories for feasibility reasons. Although we recognize that other disease activity measures have become available since the ACR endorsed 6 measures in its 2012 paper (16), it was outside the scope of this guideline effort to reevaluate measures and recommend to the ACR an updated list for possible endorsement.

A targeted literature search was performed for biosimilars, but there was too little evidence for the panel to provide recommendations on this complex issue at present. In addition, at the time of panel voting, biosimilars for RA were not yet approved for use in the US. The ACR has published a position statement on biosimilars (available at http://www.rheumatology.org/Practice-Quality/Administrative-Support/Position-Statements) that may provide some guidance for interested readers. The team recommended that biosimilars in RA therapy should be considered for future research agendas and RA guideline efforts.

The team also discussed the following topics and recommended that they be targeted for future research: use of biologics and DMARDs during the period of conception, pregnancy, and breastfeeding; treatment of RA with interstitial lung disease; laboratory monitoring for biologics/tofacitinib; and biomarker testing.

The 2015 ACR RA treatment recommendations apply to common clinical situations, since the panel considered issues common to most patients, not exceptions. In an effort to standardize terminology, the ACR has asked that the term "guideline" be used when referring to a guideline paper and the term "recommendation" when referring to an individual recommendation statement within the guideline paper. The use of the term "guideline" should not be construed as a mandate that every clinician/patient should follow the recommendations made in every clinical situation. These recommendations are not proscriptive and should be used by clinicians and patients as a guide for discussion related to RA treatments. Only a clinician's assessment, an active patient-physician dialogue, and collaborative decision-making will result in the optimal risk/benefit analysis. The best treatment decisions will be made by clinicians incorporating patients' values and preferences. Thus, the choice of the best treatment in some cases may be other options in the algorithm/recommendation rather than the first option in the treatment recommendation algorithm.

These recommendations are not intended to support payment or insurance decisions and should not be used for denial of treatments to patients. These recommendations cannot adequately convey all uncertainties and nuances of patient care in the real world. For example, a listing of all conditions entertained in each conditional recommendation is not feasible. We also noted that for newer drugs (e.g., tofacitinib), long-term experience and safety data are usually lacking, and additional data are needed to increase the confidence of clinicians in utilizing such medications.

In conclusion, the 2015 ACR RA pharmacologic treatment guideline is comprehensive and provides guidance to clinicians and patients regarding the treatment of RA. Using state-of-the-art methodology (GRADE) and a well-defined group-consensus technique, our guideline development process was systematic, explicit, and transparent. Periodic updates of this guideline, as required by the ACR for all of its guidelines, will ensure that this RA treatment guideline remains current and usable for patients and physicians for treatment decision-making in RA. Finally, the 2015 ACR RA treatment guideline is a useful tool not only to guide treatment in clinical practice but also to facilitate discussion about individualized treatment decision-making between patients and their clinicians.

ACKNOWLEDGMENTS

We thank Ms Regina Parker (ACR staff) for assistance in organizing the face-to-face meeting and coordinating the administrative aspects of the project, Ms Janet Joyce for help in developing the literature search strategy and performing the literature search and updates, and Ms Tamara Radar for peer reviewing the literature search strategy. We thank William Sanchez, MD (Consultant, Department of Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN) for providing expert advice regarding treatment of RA in the presence of hepatitis B or C.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Dr. Singh had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study conception and design. Singh, Saag, Bridges, Akl, Bannuru, Sullivan, Vaysbrot, McNaughton, Osani, Shmerling, Curtis, Furst, Parks, Kavanaugh, O'Dell, King, Leong, Matteson, Schousboe, Drevlow, Ginsberg, Grober, St.Clair, Tindall, Miller, McAlindon.

Acquisition of data. Singh, Saag, Bridges, Akl, Bannuru, Sullivan, Vaysbrot, McNaughton, Osani, Shmerling, Curtis, Furst, Parks, Kavanaugh, O'Dell, King, Leong, Matteson, Schousboe, Drevlow, Ginsberg, Grober, St.Clair, Tindall, Miller, McAlindon.

Analysis and interpretation of data. Singh, Saag, Bridges, Akl, Bannuru, Sullivan, Vaysbrot, McNaughton, Osani, Shmerling, Curtis, Furst, Parks, Kavanaugh, O'Dell, King, Leong, Matteson, Schousboe, Drevlow, Ginsberg, Grober, St.Clair, Tindall, Miller, McAlindon.

2019 Update of the American College of Rheumatology/ Spondylitis Association of America/Spondyloarthritis Research and Treatment Network Recommendations for the Treatment of Ankylosing Spondylitis and Nonradiographic Axial Spondyloarthritis

Michael M. Ward,[1] Atul Deodhar,[2] Lianne S. Gensler,[3] Maureen Dubreuil,[4] David Yu,[5] Muhammad Asim Khan,[6] Nigil Haroon,[7] David Borenstein,[8] Runsheng Wang,[9] Ann Biehl,[1] Meika A. Fang,[10] Grant Louie,[11] Vikas Majithia,[12] Bernard Ng,[13] Rosemary Bigham,[14] Michael Pianin,[15] Amit Aakash Shah,[16] Nancy Sullivan,[17] Marat Turgunbaev,[16] Jeff Oristaglio,[17] Amy Turner,[16] Walter P. Maksymowych,[18] and Liron Caplan[19]

Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide guidance for particular patterns of practice and not to dictate the care of a particular patient. The ACR considers adherence to the recommendations within this guideline to be voluntary, with the ultimate determination regarding their application to be made by the health care provider in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed and endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. ACR recommendations are not intended to dictate payment or insurance decisions. These recommendations cannot adequately convey all uncertainties and nuances of patient care.

The American College of Rheumatology is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To update evidence-based recommendations for the treatment of patients with ankylosing spondylitis (AS) and nonradiographic axial spondyloarthritis (SpA).

Methods. We conducted updated systematic literature reviews for 20 clinical questions on pharmacologic treatment addressed in the 2015 guidelines, and for 26 new questions on pharmacologic treatment, treat-to-target strategy, and use of imaging. New questions addressed the use of secukinumab, ixekizumab, tofacitinib, tumor necrosis factor inhibitor (TNFi) biosimilars, and biologic tapering/discontinuation, among others. We used the Grading of Recommendations, Assessment, Development and Evaluation methodology to assess the quality of evidence and formulate recommendations and required at least 70% agreement among the voting panel.

Results. Recommendations for AS and nonradiographic axial SpA are similar. TNFi are recommended over secukinumab or ixekizumab as the first biologic to be used. Secukinumab or ixekizumab is recommended over the use of a second TNFi in patients with primary nonresponse to the first TNFi. TNFi, secukinumab, and ixekizumab are favored over tofacitinib. Co-administration of low-dose methotrexate with TNFi is not recommended, nor is a strict treat-to-target strategy or discontinuation or tapering of biologics in patients with stable disease. Sulfasalazine is recommended only for persistent peripheral arthritis when TNFi are contraindicated. For patients with unclear disease activity, spine or pelvis magnetic resonance imaging could aid assessment. Routine monitoring of radiographic changes with serial spine radiographs is not recommended.

Conclusion. These recommendations provide updated guidance regarding use of new medications and imaging of the axial skeleton in the management of AS and nonradiographic axial SpA.

INTRODUCTION

Axial spondyloarthritis (SpA), comprising ankylosing spondylitis (AS) and nonradiographic axial SpA, is the main form of chronic inflammatory arthritis affecting the axial skeleton (1). AS affects 0.1–0.5% of the population, and is characterized by inflammatory back pain, radiographic sacroiliitis, excess spinal bone formation, and a high prevalence of HLA–B27 (2,3). Although nonradiographic axial SpA shares several features with AS, advanced sacroiliac joint damage and spine ankylosis are absent (4). The severity of arthralgia, stiffness, and limited flexibility varies widely among patients and over the course of axial SpA. Skeletal disease may be accompanied by uveitis, psoriasis, and inflammatory bowel disease (IBD). Axial SpA can impose substantial physical and social burdens on patients, and can interfere with work and schooling (5,6). The goals of treatment are to alleviate symptoms, improve functioning, maintain the ability to work, decrease disease complications, and forestall skeletal damage as much as possible.

In 2015, the American College of Rheumatology (ACR), Spondylitis Association of America (SAA), and Spondyloarthritis Research and Treatment Network (SPARTAN) published recommendations for the treatment of adults with AS and those with nonradiographic axial SpA (7). Recommendations were provided for pharmacologic treatment, rehabilitation, use of surgery, management of selected comorbidities, disease monitoring, patient education, and preventive care. The recommendations were tailored to patients with either active or stable disease and focused on the most common decisions confronting clinicians when treating these patients.

The advent of new medications to treat axial SpA warranted this update. We did not reexamine all of the 2015 recommendations, but rather focused on those questions for which consequential new evidence was present. We added several new recommendations on how the newly available medications should fit in treatment strategies and on the use of imaging. The target populations are adults with AS or nonradiographic axial SpA. The target users of these recommendations are rheumatologists, primary care clinicians, physiatrists, physical therapists, and others providing care to patients with axial SpA.

METHODS

These recommendations followed ACR and Grading of Recommendations, Assessment, Development and Evaluation (GRADE) methodology (8,9), as described in Supplementary Appendix 1, available on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract. Briefly, systematic literature reviews were done for prespecified clinical population, intervention, comparator, outcomes (PICO) questions. The resulting evidence was reviewed, and recommendations formulated and voted on, by an expert voting panel (see Supplementary Appendices 2–5 at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). Key definitions, including ones for active and stable disease, are provided in Table 1. Clinical trials of ixekizumab became available during the time the manuscript was in preparation, after the voting panel had met (10,11). The data from these trials were provided to the voting panel, and revised recommendations that included ixekizumab were reviewed and voted on by the panel.

Table 1. Definitions of key terms*

Term	Definition
Active disease	Disease causing symptoms at an unacceptably bothersome level to the patient and judged by the examining clinician to be due to inflammation.
Stable disease	Disease that was asymptomatic or causing symptoms but at an acceptable level as reported by the patient. A minimum of 6 months was required to qualify as clinically stable.
Primary nonresponse	Absence of a clinically meaningful improvement in disease activity over the 3 to 6 months after treatment initiation, not related to toxicity or poor adherence.
Secondary nonresponse	Recurrence of ankylosing spondylitis activity, not due to treatment interruption or poor adherence, after having a sustained clinically meaningful improvement on treatment (generally, beyond the initial 6 months of treatment).
Conventional synthetic antirheumatic drug	Sulfasalazine, methotrexate, leflunomide, apremilast, thalidomide, pamidronate.
Biosimilar	Biopharmaceuticals that are copies of an original biologic medication and tested to be of the same purity and potency as the original. In these recommendations, we refer only to TNFi biosimilars. Examples include infliximab-dyyb, etanercept-szzs, and adalimumab-atto.
TNFi	Infliximab, etanercept, adalimumab, certolizumab, golimumab, and their biosimilars.
TNFi monoclonal antibodies	Infliximab, adalimumab, certolizumab, golimumab.
Biologics	TNFi, abatacept, rituximab, sarilumab, tocilizumab, ustekinumab, secukinumab, ixekizumab.**
High-quality evidence	Studies that provide high confidence in the effect estimate, and new data from future studies are thought unlikely to change the effect.
Moderate-quality evidence	Studies that provide confidence that the true effect is likely to be close to the estimate but could be substantially different.
Low-quality evidence	Studies that provide limited confidence about the effect, and the true effect may be substantially different from the estimate.
Very low-quality evidence	Studies that provide very little certainty about the effect, and the true effect may be quite different from the estimate.
Strong recommendation	Action should be favored in almost all patients, usually requiring high-quality evidence, high confidence that future research will not alter the conclusion, AND an assessment that the desirable effects of the intervention outweigh the undesirable effects. Should not be taken to imply that the intervention has large clinical benefits.
Conditional recommendation	Action should be followed in only selected cases, often limited by low-quality evidence, OR when the desirable and undesirable consequences of an intervention are more balanced, OR if patients' preferences for the intervention are thought to vary widely.
Patient preferences	Beliefs and expectations regarding potential benefits and harms of treatment and how these relate to an individual's goals for health and life.
Shared decision-making	The process by which a patient and clinician arrive at an individualized treatment decision based on an understanding of the potential benefits and risks of available treatment options and of a patient's values and preferences.

* TNFi = tumor necrosis factor inhibitor.

RESULTS

Here we present the recommendations that were reviewed in this update, whether it was a new recommendation (designated "new") or reevaluation of an existing recommendation. Table 2 and Table 3 provide all current recommendations, including those from the 2015 report that were not newly reviewed. The order of recommendations presented here does not imply priority for use or recommended sequencing of different interventions. PICO numbers following each recommendation can be used to locate related evidence in Supplementary Appendix 6, available on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract.

**Correction added on 26 September 2019, after first online publication: Secukinumab and ixekizumab were omitted in Table 1. They have been restored in this version of the article.

A. Recommendations for the treatment of patients with active AS

In adults with active AS, we conditionally recommend continuous treatment with nonsteroidal antiinflammatory drugs (NSAIDs) over on-demand treatment with NSAIDs (PICO 1).

The efficacy of NSAIDs for symptom improvement in active AS has been established in many controlled trials. Evidence that continuous NSAID use results in slower rates of spinal fusion on radiographs over 2 years compared to on-demand NSAID use is inconsistent, with results of one trial of celecoxib suggesting less progression with continuous use, and one trial of diclofenac indicating no difference in progression (12,13) (See Supplementary Appendix 6, available on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). Despite the

Table 2. Recommendations for the treatment of adults with AS*

Recommendation	Level of evidence	PICO
RECOMMENDATIONS FOR ADULTS WITH ACTIVE AS		
1. We strongly recommend treatment with NSAIDs over no treatment with NSAIDs.†	Low	2
2. We conditionally recommend continuous treatment with NSAIDs over on-demand treatment with NSAIDs.	Low to moderate	1
3. We do not recommend any particular NSAID as the preferred choice.†	Low to moderate	3
4. In adults with active AS despite treatment with NSAIDs, we conditionally recommend treatment with sulfasalazine, methotrexate, or tofacitinib over no treatment with these medications. Sulfasalazine or methotrexate should be considered only in patients with prominent peripheral arthritis or when TNFi are not available.	Very low to moderate	7
5. In adults with active AS despite treatment with NSAIDs, we conditionally recommend treatment with TNFi over treatment with tofacitinib.	Very low	60
6. In adults with active AS despite treatment with NSAIDs, we strongly recommend treatment with TNFi over no treatment with TNFi.	High	6
7. We do not recommend any particular TNFi as the preferred choice.	Moderate	5
8. In adults with active AS despite treatment with NSAIDs, we strongly recommend treatment with secukinumab or ixekizumab over no treatment with secukinumab or ixekizumab.	High	58
9. In adults with active AS despite treatment with NSAIDs, we conditionally recommend treatment with TNFi over treatment with secukinumab or ixekizumab.	Very low	59
10. In adults with active AS despite treatment with NSAIDs, we conditionally recommend treatment with secukinumab or ixekizumab over treatment with tofacitinib.	Very low	61
11. In adults with active AS despite treatment with NSAIDs and who have contraindications to TNFi, we conditionally recommend treatment with secukinumab or ixekizumab over treatment with sulfasalazine, methotrexate, or tofacitinib.	Low	8
12. In adults with active AS despite treatment with the first TNFi used, we conditionally recommend treatment with secukinumab or ixekizumab over treatment with a different TNFi in patients with primary nonresponse to TNFi.	Very low	10
13. In adults with active AS despite treatment with the first TNFi used, we conditionally recommend treatment with a different TNFi over treatment with a non-TNFi biologic in patients with secondary nonresponse to TNFi.	Very low	10
14. In adults with active AS despite treatment with the first TNFi used, we strongly recommend against switching to treatment with a biosimilar of the first TNFi.	Very low	62
15. In adults with active AS despite treatment with the first TNFi used, we conditionally recommend against the addition of sulfasalazine or methotrexate in favor of treatment with a new biologic.	Very low	9
16. We strongly recommend against treatment with systemic glucocorticoids.†	Very low	4
17. In adults with isolated active sacroiliitis despite treatment with NSAIDs, we conditionally recommend treatment with locally administered parenteral glucocorticoids over no treatment with local glucocorticoids.†	Very low	13
18. In adults with stable axial disease and active enthesitis despite treatment with NSAIDs, we conditionally recommend using treatment with locally administered parenteral glucocorticoids over no treatment with local glucocorticoids. Peri-tendon injections of Achilles, patellar, and quadriceps tendons should be avoided.†	Very low	14
19. In adults with stable axial disease and active peripheral arthritis despite treatment with NSAIDs, we conditionally recommend using treatment with locally administered parenteral glucocorticoids over no treatment with local glucocorticoids.†	Very low	15
20. We strongly recommend treatment with physical therapy over no treatment with physical therapy.†	Moderate	16
21. We conditionally recommend active physical therapy interventions (supervised exercise) over passive physical therapy interventions (massage, ultrasound, heat).†	Very low	17
22. We conditionally recommend land-based physical therapy interventions over aquatic therapy interventions.†	Moderate	18
RECOMMENDATIONS FOR ADULTS WITH STABLE AS		
23. We conditionally recommend on-demand treatment with NSAIDs over continuous treatment with NSAIDs.	Low to moderate	1
24. In adults receiving treatment with TNFi and NSAIDs, we conditionally recommend continuing treatment with TNFi alone compared to continuing both treatments.	Very low	11
25. In adults receiving treatment with TNFi and a conventional synthetic antirheumatic drug, we conditionally recommend continuing treatment with TNFi alone over continuing both treatments.	Very low	12
26. In adults receiving treatment with a biologic, we conditionally recommend against discontinuation of the biologic.	Very low to low	66

(Continued)

Table 2. (*Cont'd*)

Recommendation	Level of evidence	PICO
27. In adults receiving treatment with a biologic, we conditionally recommend against tapering of the biologic dose as a standard approach.	Very low to low	65
28. In adults receiving treatment with an originator TNFi, we strongly recommend continuing treatment with the originator TNFi over mandated switching to its biosimilar.	Very low	63
29. We strongly recommend treatment with physical therapy over no treatment with physical therapy.†	Low	19
RECOMMENDATIONS FOR ADULTS WITH ACTIVE OR STABLE AS		
30. In adults receiving treatment with TNFi, we conditionally recommend against co-treatment with low-dose methotrexate.	Low	64
31. We conditionally recommend advising unsupervised back exercises.†	Moderate	20
32. We conditionally recommend fall evaluation and counseling.†	Very low	51
33. We conditionally recommend participation in formal group or individual self-management education.†	Moderate	48
34. In adults with spinal fusion or advanced spinal osteoporosis, we strongly recommend against treatment with spinal manipulation.†	Very low	21
35. In adults with advanced hip arthritis, we strongly recommend treatment with total hip arthroplasty over no surgery.†	Very low	25
36. In adults with severe kyphosis, we conditionally recommend against elective spinal osteotomy.†	Very low	26
RECOMMENDATIONS FOR ADULTS WITH AS-RELATED COMORBIDITIES		
37. In adults with acute iritis, we strongly recommend treatment by an ophthalmologist to decrease the severity, duration, or complications of episodes.†	Very low	27
38. In adults with recurrent iritis, we conditionally recommend prescription of topical glucocorticoids over no prescription for prompt at-home use in the event of eye symptoms to decrease the severity or duration of iritis episodes.†	Very low	28
39. In adults with recurrent iritis, we conditionally recommend treatment with TNFi monoclonal antibodies over treatment with other biologics.	Low	29
40. In adults with inflammatory bowel disease, we do not recommend any particular NSAID as the preferred choice to decrease the risk of worsening of inflammatory bowel disease symptoms.†	Very low	31
41. In adults with inflammatory bowel disease, we conditionally recommend treatment with TNFi monoclonal antibodies over treatment with other biologics.	Very low	32
DISEASE ACTIVITY ASSESSMENT, IMAGING, AND SCREENING		
42. We conditionally recommend the regular-interval use and monitoring of a validated AS disease activity measure.†	Very low	54
43. We conditionally recommend regular-interval use and monitoring of CRP concentrations or ESR over usual care without regular CRP or ESR monitoring.†	Very low	55
44. In adults with active AS, we conditionally recommend against using a treat-to-target strategy using a target of ASDAS <1.3 (or 2.1) over a treatment strategy based on physician assessment.	Low	67
45. We conditionally recommend screening for osteopenia/osteoporosis with DXA scan over no screening.†	Very low	49
46. In adults with syndesmophytes or spinal fusion, we conditionally recommend screening for osteoporosis/osteopenia with DXA scan of the spine as well as the hips, compared to DXA scan solely of the hip or other non-spine sites.†	Very low	50
47. We strongly recommend against screening for cardiac conduction defects with electrocardiograms.†	Very low	52
48. We strongly recommend against screening for valvular heart disease with echocardiograms.†	Very low	53
49. In adults with AS of unclear activity while on a biologic, we conditionally recommend obtaining a spinal or pelvis MRI to assess activity.	Very low	68
50. In adults with stable AS, we conditionally recommend against obtaining a spinal or pelvis MRI to confirm inactivity.	Very low	69
51. In adults with active or stable AS on any treatment, we conditionally recommend against obtaining repeat spine radiographs at a scheduled interval (e.g., every 2 years) as a standard approach.	Very low	70

* AS = ankylosing spondylitis; PICO = population, intervention, comparison, and outcomes; NSAIDs = nonsteroidal antiinflammatory drugs; TNFi = tumor necrosis factor inhibitor; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; ASDAS = Ankylosing Spondylitis Disease Activity Score; DXA = dual x-ray absorptiometry; MRI = magnetic resonance imaging.

* SpA = spondyloarthritis; PICO = population, intervention, comparison, and outcomes; NSAIDs = nonsteroidal antiinflammatory drugs; TNFi = tumor necrosis factor inhibitor; AS = ankylosing spondylitis; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; ASDAS = Ankylosing Spondylitis Disease Activity Score; MRI = magnetic resonance imaging.
† These recommendations were from 2015 and were not reviewed in this update. The number preceding the recommendation is the recommendation number and is referenced as bracketed numbers in Figure 1.

uncertainty regarding potential disease-modifying effects, the committee conditionally favored continuous use of NSAIDs in patients with active AS, primarily for controlling disease activity. The decision to use NSAIDs continuously may vary depending on the severity of symptoms, patient preferences, and comorbidities, particularly gastrointestinal and kidney comorbidities, and cardiovascular disease.

In adults with active AS despite treatment with NSAIDs, we conditionally recommend treatment with sulfasalazine, methotrexate, or tofacitinib over no treatment with these medications (new, PICO 7). Sulfasalazine or methotrexate should be considered only in patients with prominent peripheral arthritis or when tumor necrosis factor inhibitors (TNFi) are not available.

Treatment with sulfasalazine is recommended primarily for patients with prominent peripheral arthritis and few or no axial symptoms. However, TNFi may provide a better option for these patients. Evidence for the efficacy of sulfasalazine is based on 8 older controlled trials that showed benefit for peripheral arthritis (see Supplementary Appendix 6, on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). Although a recent placebo-controlled trial of sulfasalazine demonstrated improvement in axial symptoms, and modest clinical and imaging responses were seen in a second trial, the preponderance of evidence indicates that sulfasalazine has little benefit for axial symptoms (14,15). Sulfasalazine may have a role in treating patients who have contraindications to TNFi, those who decline treatment with TNFi, or those with limited access to TNFi.

Three trials of methotrexate with negative results tested doses of ≤10 mg weekly, and the lack of benefit may reflect the low doses used (16–18). One uncontrolled study of methotrexate 20 mg weekly showed no improvement in axial symptoms, but a decrease in swollen joint count (19). Treatment with methotrexate may be considered for patients with predominately peripheral arthritis, although among nonbiologics, there is more evidence supporting the use of sulfasalazine.

A phase II study of tofacitinib showed benefit in both clinical and imaging outcomes of axial disease over 12 weeks (20). Use of tofacitinib could be another option, although the results of phase III trials are not available. Leflunomide, apremilast, thalidomide, and pamidronate are not recommended (See Supplementary Appendix 6, available on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract).

In adults with active AS despite treatment with NSAIDs, we strongly recommend treatment with TNFi over no treatment with TNFi (PICO 6).

In adults with active AS despite treatment with NSAIDs, we do not recommend any particular TNFi as the preferred choice (PICO 5).

The efficacy of TNFi in patients with active AS has been demonstrated in 24 randomized controlled trials, most of which were short-term (6 months or shorter) placebo-controlled studies. Improvements were shown in patient-reported outcomes, composite response criteria, and spine and sacroiliac inflammation on magnetic resonance imaging (MRI) (see Supplementary Appendix 6, on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). The panel judged that the evidence justified a strong recommenda-

tion for use of TNFi in patients whose AS remained active (as defined in Table 1) despite treatment with NSAIDs. The panel recommended that lack of response (or intolerance) to at least 2 different NSAIDs at maximal doses over 1 month, or incomplete responses to at least 2 different NSAIDs over 2 months, would be adequate trials with which to judge NSAID responsiveness prior to escalating to treatment with TNFi.

Indirect comparisons in network meta-analyses of clinical trials have not showed clinically meaningful differences in short-term efficacy among TNFi in the treatment of active AS (see Supplementary Appendix 6, at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract) (21). Direct comparisons among these medications are limited to a trial of infliximab versus its biosimilar, and a very small open-label trial of infliximab versus etanercept (22,23). The panel judged that the evidence did not support preference of 1 TNFi over any other for the typical patient. Important exceptions apply to patients with recurrent uveitis or coexistent IBD (see PICO 29 and PICO 32 below). Patients treated with infliximab may have increased risks of tuberculosis and of infections generally (24,25). TNFi other than infliximab should be considered for patients at higher risk of tuberculosis exposure (either through travel or household contacts) or with a history of recurrent infections. Patient preferences regarding the frequency of dosing and route of administration should be weighed when selecting a specific TNFi.

In adults with active AS despite treatment with NSAIDs, we strongly recommend treatment with secukinumab or ixekizumab over no treatment with secukinumab or ixekizumab (new, PICO 58).

In adults with active AS despite treatment with NSAIDs, we conditionally recommend treatment with TNFi over treatment with secukinumab or ixekizumab (new, PICO 59).

In adults with active AS despite treatment with NSAIDs, we conditionally recommend treatment with TNFi over treatment with tofacitinib (new, PICO 60).

In adults with active AS despite treatment with NSAIDs, we conditionally recommend treatment with secukinumab or ixekizumab over treatment with tofacitinib (new, PICO 61).

The use of secukinumab and ixekizumab in patients with active AS is supported by data from large placebo-controlled trials (see Supplementary Appendix 6, on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). The panel recommended use of TNFi over secukinumab or ixekizumab based on greater experience with TNFi and familiarity with their long-term safety and toxicity. Similarly, the panel judged that TNFi, secukinumab, or ixekizumab should be used over tofacitinib, given the larger evidence base for TNFi, secukinumab, and ixekizumab. In patients with coexisting ulcerative colitis, if treatment with TNFi is not an option, tofacitinib should be considered over secukinumab or ixekizumab. Interleukin-17 (IL-17) inhibitors have not been shown to be efficacious in IBD, although tofacitinib is an approved treatment for ulcerative colitis (26,27).

In adults with active AS despite treatment with NSAIDs and who have contraindications to TNFi, we conditionally recommend treatment with secukinumab or ixekizumab over treatment with sulfasalazine, methotrexate, or tofacitinib (new, PICO 8).

No studies have directly compared the risks and benefits of treatment alternatives in patients who have contraindications to treatment with TNFi. The panel favored treatment with secukinumab or ixekizumab over treatment with sulfasalazine or methotrexate based on a higher likelihood of benefit, but this recommendation was conditional on the specific contraindication. If the contraindication to TNFi use was the presence of congestive heart failure or demyelinating disease, secukinumab or ixekizumab was preferred, since these medications have not been shown to worsen these conditions. If the contraindication to TNFi use was tuberculosis, other chronic infection, or a high risk of recurrent infections, sulfasalazine was preferred over secukinumab, izekizumab, and tofacitinib. In these cases, efforts to mitigate the infections should be undertaken so that TNFi might safely be used. Treatment with rituximab, abatacept, ustekinumab, or IL-6 inhibitors is not recommended, even in patients with contraindications to TNFi, due to lack of effectiveness.

In adults with active AS despite treatment with the first TNFi used, we conditionally recommend treatment with secukinumab or ixekizumab over treatment with a different TNFi in patients with primary nonresponse to TNFi (new, PICO 10).

In adults with active AS despite treatment with the first TNFi used, we conditionally recommend treatment with a different TNFi over treatment with a non-TNFi biologic in patients with secondary nonresponse to TNFi (new, PICO 10).

In adults with active AS despite treatment with the first TNFi used, we strongly recommend against switching to treatment with a biosimilar of the first TNFi (new, PICO 62).

In adults with active AS despite treatment with the first TNFi used, we conditionally recommend against the addition of sulfasalazine or methotrexate in favor of switching to a new biologic (PICO 9).

Direct comparisons of treatment strategies for patients who do not have or sustain adequate responses to their first TNFi have not been reported, and the recommendations are based on the panel's consideration of indirect comparisons among the available treatment options (see Supplementary Appendix 6, at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). Data from observational studies suggest that 25–40% of patients who switch from one TNFi to another will have a meaningful response (e.g.,

50% improvement in Bath AS Disease Activity Index) to the second TNFi (28–30). However, not all patients in these studies switched TNFi because of ineffectiveness.

The panel judged that treatment should differ for patients who had a primary nonresponse to TNFi and those with secondary nonresponse to TNFi. Switching to secukinumab or ixekizumab was recommended in most patients who had a primary nonresponse to the first TNFi, under the assumption that TNF was not the key inflammatory mediator in these patients. Continuing treatment with the first TNFi could be considered if additional time was believed important to assess the response fully, or if a higher dose or shorter dosing interval was thought to be beneficial.

In patients who relapse after an initial response (i.e., secondary nonresponse), the panel judged that treatment with a different TNFi held a reasonable prospect of benefit and should be used in most patients, rather than immediately switching to a different class of biologics. Although ixekizumab is efficacious among TNFi nonresponders, trials have not directly compared responses to ixekizumab (or secukinumab) to responses to a second TNFi in patients with a secondary nonresponse to the first TNFi (11). Given that options for biologics are limited, treatment with a second TNFi was recommended in these patients.

In cases of nonresponse (primary or secondary), the panel recommended against switching to the biosimilar of the first TNFi (e.g., switching from originator infliximab to infliximab-dyyb), as the clinical response would not be expected to be different. The panel also recommended against the addition of sulfasalazine or methotrexate to TNFi in cases of nonresponse to TNFi, judging any benefit would likely be marginal. The addition of sulfasalazine could be considered in the rare patient whose axial symptoms are well-controlled with TNFi but who has active peripheral arthritis.

In adults with either active or stable AS on treatment with TNFi, we conditionally recommend against co-treatment with low-dose methotrexate (new, PICO 64).

In rheumatoid arthritis, the likelihood of TNFi discontinuation is lower among patients who receive co-treatment with methotrexate, perhaps by reducing the development of antidrug antibodies (31). In AS, it is less clear whether the duration of TNFi use, and by inference their effectiveness, is similarly prolonged (32). Data from observational studies are conflicting, although some studies, primarily of infliximab, showed longer TNFi treatment when methotrexate was co-administered (see Supplementary Appendix 6 at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). Clinical responses were not greater among patients who received co-treatment with methotrexate. In the absence of convincing evidence of benefit, and due to greater burden for patients, the panel recommended against routine co-administration of methotrexate with TNFi, although its use could be considered in patients treated with infliximab.

B. Recommendations for the treatment of patients with stable AS

In adults with stable AS, we conditionally recommend on-demand treatment with NSAIDs over continuous treatment with NSAIDs (PICO 1).

This recommendation applies to patients whose AS has been stable while not receiving any pharmacologic treatment. In this group, the panel considered that the potential toxicities of continuous NSAID treatment outweighed the uncertain benefit of less radiographic progression. On-demand treatment should be considered for short-term symptom recurrences (flares).

In adults with stable AS receiving treatment with TNFi and NSAIDs, we conditionally recommend continuing treatment with TNFi alone over continuing both medications (PICO 11).

In adults with stable AS receiving treatment with TNFi and a conventional synthetic antirheumatic drug, we conditionally recommend continuing treatment with TNFi alone over continuing both medications (PICO 12).

No new studies have directly compared outcomes between patients who continued combination treatment and those who discontinued either NSAIDs or a conventional synthetic antirheumatic drug (csARD). The NSAID-sparing potential of etanercept was demonstrated in a recent trial (33). The panel judged these recommendations primarily based on symptom control, rather than on any potential effect of combination therapy on future spinal fusion. In stable patients, a trial of withdrawing either the NSAIDs or the csARD should be considered, due to the likelihood of greater toxicity with the long-term use of more than one medication. However, on-demand NSAID treatment for control of intermittent symptoms is recommended for patients with good responses to previous courses of NSAIDs.

In adults with stable AS receiving treatment with a biologic, we conditionally recommend against discontinuation of the biologic (new, PICO 66).

In adults with stable AS receiving treatment with a biologic, we conditionally recommend against tapering of the biologic dose as a standard approach (new, PICO 65).

Data from several observational studies suggest that discontinuation of TNFi after achieving either remission or low disease activity results in relapses in 60–74% of patients, occasionally within a few weeks to months from discontinuation (see Supplementary Appendix 6, available at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). Although the data only concerned TNFi discontinuation, the panel judged that a similar recommendation would also apply to other biologics. In general, treatment with a biologic should be planned to be

continued long-term, barring toxicities. Discontinuation might be considered in patients in sustained remission (i.e., several years), with the anticipation that only one-third of patients would not experience relapse. Patient preferences should help guide this decision.

Tapering of TNFi could entail a change in either the dose or frequency of administration. Two controlled unblinded trials of tapering etanercept to 25 mg weekly versus maintaining the dose at 50 mg weekly in patients with stable AS showed that remission or partial remission was somewhat less likely among those in whom etanercept was tapered (34,35). In small observational studies, 53–70% of patients were still receiving their reduced dose at 2 years, but there is little evidence regarding maintenance of long-term remission after tapering of TNFi (see Supplementary Appendix 6, available at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). Therefore, the panel recommended against tapering of biologics as a standard approach. One condition in which tapering could be considered would be in patients with prolonged stable AS, if the patient and provider engage in shared decision-making.

In adults with stable AS receiving an originator TNFi, we strongly recommend continuing treatment with the originator TNFi over mandated switching to its biosimilar (new, PICO 63).

While the efficacy of originator and biosimilar TNFi is comparable, and although either could be chosen to initiate new courses of TNFi treatment, it was the opinion of the panel to recommend against mandated switching to a biosimilar during the course of treatment, in the absence of evidence of interchangability. Medication changes can increase the risk of destabilizing a patient's condition, and the panel judged that additional data were needed to understand the frequency of potential problems and concerns associated with switching patients who were stable on an originator TNFi to its biosimilar. Given these concerns, the panel judged that there should be a compelling rationale for switching medications, particularly in light of the marginal cost savings apparent for US patients (36).

C. Recommendations for adults with AS-related comorbidities

In adults with AS and recurrent uveitis, we conditionally recommend treatment with TNFi monoclonal antibodies over treatment with other biologics (PICO 29).

Evidence for this recommendation is limited to indirect comparisons of the rates of acute uveitis episodes in clinical trials or observational studies, rather than from direct comparisons (see Supplementary Appendix 6, available at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). Many reports showed overall rates of uveitis without separately reporting recurrences as opposed to incident episodes (37). The rates were generally lower for adalimumab and infliximab compared to etanercept. For example, a large observational study demonstrated rates of uveitis (per 100 patient-years) in patients receiving adalimumab, infliximab, and etanercept of 13.6, 27.5, and 60.3, respectively, compared to pretreatment rates of 36.8, 45.5, and 41.6, respectively (38). Adalimumab or infliximab are preferred over etanercept for the treatment of AS in patients with recurrent uveitis. Certolizumab or golimumab may also be considered, although supporting data are less substantial (39,40). Data from clinical trials suggest that rates of uveitis flares were not different between patients with AS treated with secukinumab and those treated with placebo, but more evidence is needed. Secukinumab was not efficacious in the treatment of panuveitis or posterior uveitis (41). Rates of uveitis flares among patients treated with ixekizumab have not been well-defined.

In adults with AS and IBD, we conditionally recommend treatment with TNFi monoclonal antibodies over treatment with other biologics (PICO 32).

This recommendation was based on limited indirect evidence on the risks of flares or new onset of IBD among patients with AS during treatment with biologics, and the much larger literature on the treatment of IBD in general. Patients with AS treated with infliximab or adalimumab have lower risks of IBD exacerbations than those treated with etanercept (see Supplementary Appendix 6, on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). Infliximab, adalimumab, and certolizumab are approved for the treatment of Crohn's disease, and infliximab, adalimumab, and golimumab are approved for the treatment of ulcerative colitis, while etanercept is not approved for either condition (42,43). This evidence is the basis for the recommendation favoring TNFi monoclonal antibody use in patients with AS and coexisting IBD. The choice of the particular TNFi monoclonal antibody should be made in consultation with the patient's gastroenterologist. Secukinumab has been associated with the new onset, or exacerbation, of Crohn's disease (44–46). Increased risks of IBD exacerbation appear to also occur with ixekizumab (47).

D. Recommendations for the treatment of patients with either active or stable nonradiographic axial spondyloarthritis

Parallel questions on pharmacologic treatment were investigated for patients with nonradiographic axial SpA. There were no relevant published data for 19 questions. There was high-quality evidence only for the use of TNFi in nonradiographic axial SpA, which was examined in several clinical trials. Low-quality or very low-quality evidence from single studies suggested no differences in outcomes among different TNFi in nonradiographic axial SpA, high likelihood of relapse following discontinuation of TNFi, and no association between co-treatment with nonbiologics and TNFi persistence (see Supplementary Appendix 6, available at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract).

Therefore, the recommendations for nonradiographic axial SpA were largely extrapolated from evidence in AS (Table 3). The recommendations were identical in both patient groups with 1 notable exception: treatment with secukinumab or ixekizumab was strongly recommended over no treatment with secukinumab or ixekizumab in patients with AS, while use of these medications was conditionally recommended in patients with nonradiographic axial SPA, because trials in nonradiographic axial SPA have not been reported. Evidence on tofacitinib in nonradiographic axial SpA has not been reported.

E. Disease activity assessment and imaging

In adults with active AS, we conditionally recommend against using the treat-to-target strategy, which aims at a target of an Ankylosing Spondylitis Disease Activity Score <1.3 (or 2.1), over a treatment strategy based on physician assessment (new, PICO 67).

The concept of treat-to-target strategies is well-founded in chronic disease management for conditions that have an accurate measure of disease activity (often one that is asymptomatic, as in blood pressure or glycosylated hemoglobin), a tight link between this disease activity measure and future health outcomes, and evidence that maintaining a particular target in the disease activity measure is closely associated with better long-term health (48). The treat-to-target approach in AS is indirectly supported by associations between levels of AS activity and future radiographic progression but lacks robust direct evidence. Because adoption of this strategy would place additional burdens on patients and providers, the panel judged that more convincing evidence of benefit should be present before endorsing this change in practice. There was also concern that focus on a specific target could lead to rapid cycling through all currently available treatments in some patients. As reflected in the 2015 guidelines, quantifying disease activity is important to help guide treatment decisions.

In adults with AS of unclear activity while receiving a biologic, we conditionally recommend obtaining a spinal or pelvis MRI to assess activity (new, PICO 68).

In adults with nonradiographic axial SpA of unclear activity while receiving a biologic, we conditionally recommend obtaining a pelvis MRI to assess activity (new, PICO 81).

Because physical and laboratory measures are often normal despite active axial SpA, and because symptoms may be nonspecific, it may be difficult to know whether a patient is experiencing inflammation that warrants a change in treatment. Limited evidence suggests that knowledge of MRI findings in the spine and sacroiliac joints may alter treatment recommendations. However, the degree of inflammatory change on MRI may not correlate with treatment responses, and the location of inflammation on MRI may not correlate with the location of pain (49) (see Supplementary Appendix 6, available at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). The panel judged that MRI could provide useful information in cases where the level of disease activity was unclear and where this information would influence treatment decisions. For patients with nonradiographic axial SpA, the imaging should focus on the sacroiliac joints. In interpreting MRI results, it is important to keep in mind the range and frequency of abnormalities, including bone marrow edema lesions, that may occur in individuals without axial SpA and that may not represent inflammation due to axial SpA (50,51). MRI is not recommended in patients in whom disease activity is either clearly clinically active or clinically stable, or when the results of MRI would not be expected to change treatment.

In adults with stable AS, we conditionally recommend against obtaining a spinal or pelvis MRI to confirm inactivity (new, PICO 69).

In adults with stable nonradiographic axial SpA, we conditionally recommend against obtaining a spine or pelvis MRI to confirm inactivity (new, PICO 82).

Because the clinical assessment of inflammation in axial SpA has many limitations, questions may arise about whether subclinical inflammation that could be detected by MRI is being "missed" by either the physical examination, symptoms, or laboratory studies. Given the lack of evidence that obtaining an MRI in stable patients improves clinical outcomes, the only moderate sensitivity and specificity of MRI-defined abnormalities for measurement of activity in axial SpA, the burden of testing, and concern for possible overtreatment, the panel recommended against obtaining an MRI in this setting. MRI could be considered in circumstances where the clinician and patient differ in their assessment of whether the disease is stable.

In adults with active or stable AS receiving any treatment, we conditionally recommend against obtaining repeat spine radiographs at a scheduled interval (e.g., every 2 years) as a standard approach (new, PICO 70).

In adults with active or stable nonradiographic axial SpA on any treatment, we conditionally recommend against obtaining repeat spine radiographs at a scheduled interval (e.g., every 2 years) as a standard approach (new, PICO 83).

Spine radiographs are useful for the diagnosis of axial SpA, in evaluating the extent of spinal fusion, and for investigating new spinal pain in patients with established AS. In research studies, small changes in the extent of spine damage can be detected in 20–35% of patients with AS over a 2-year interval (see Supplementary Appendix 6, available at http://onlinelibrary.wiley.com/doi/10.1002/art.41042/abstract). There is no evidence that monitoring serial changes in

Figure 1. Summary of the main recommendations for the treatment of patients with **A,** active ankylosing spondylitis and **B,** stable ankylosing spondylitis. AS = ankylosing spondylitis; NSAIDs = nonsteroidal antiinflammatory drugs; GC = glucocorticoid; SSZ = sulfasalazine; MTX = methotrexate; LEF = leflunomide; APR = apremilast; THL = thalidomide; PAM = pamidronate; TNFi = tumor necrosis factor inhibitor; TOF = tofacitinib; SEC = secukinumab; IXE = ixekizumab; IBD = inflammatory bowel disease; csARD = conventional synthetic antirheumatic drugs; ESR = erythrocyte sedimentation rate; CRP = C-reactive protein level; ASDAS = Ankylosing Spondylitis Disease Activity Score; MRI = magnetic resonance imaging; PICO = population, intervention, comparison, and outcomes.

spine radiographs at a regular interval leads to better patient outcomes, and data balancing a clinical benefit with the risk of radiation exposure are absent. Therefore, the panel recommended against repeating spine radiographs as a standard approach. In the absence of clinical indications, repeat spine radiographs could be considered on an ad hoc basis for counseling patients on the progression of their disease, which may help in career and life planning.

F. Summary of recommendations

Figure 1 presents a diagram of the main treatment recommendations for active and stable AS, integrating the new recommendations with the 2015 recommendations that were not updated in this review.

DISCUSSION

This update was primarily motivated by the availability of new treatment options, notably secukinumab, ixekizumab, tofacitinib, and TNFi biosimilars, for patients with axial SpA. Providers and patients have questions on where these new medications fit in the pharmacologic strategy, and how originator TNFi, sulfasalazine, and NSAIDs should be used given these new options. Based on the current evidence and the considerations of the panel, NSAIDs and TNFi remain the primary classes of medications for the treatment of AS and nonradiographic axial SpA. Secukinumab or ixekizumab is recommended for patients with active disease who have heart failure or demyelinating disease as a contraindication to TNFi, and in primary nonresponders to TNFi. Secukinumab and ixekizumab are not recommended in patients with IBD or recurrent uveitis, as TNFi monoclonal antibodies are better options. Tofacitinib is a potential second-line option for patients with contraindications to TNFi other than infections. Recommendations regarding tofacitinib may change pending the results of larger clinical trials.

Several of the 2015 recommendations were modified in this update. The current recommendation is conditionally in favor of use of sulfasalazine in limited clinical circumstances, whereas the 2015 recommendations had this as an exception to the general recommendation against the use of conventional synthetic antirheumatic drugs. In the 2015 recommendations, sulfasalazine and pamidronate were suggested as alternatives for the treatment of patients with active disease and contraindications to TNFi, while the current recommendations suggest use of secukinumab or ixekizumab in most of these cases (except patients with high risk of infections). In cases of failure of TNFi, the 2015 guidelines included a conditional recommendation for a trial of a second TNFi and against use of a non-TNFi biologic, whereas the current guidelines differentiate treatment recommendations based on whether there was primary or secondary nonresponse to the TNFi. For the treatment of patients with recurrent uveitis, the previous guidelines specified conditional use of infliximab or adalimumab, while the update broadened this recommendation to include TNFi monoclonal antibodies generally. Similarly, for patients with coexisting IBD, the update includes a conditional recommendation for TNFi monoclonal antibodies over other biologics, rather than over only etanercept. Finally, the recommendation for use of TNFi in patients with active nonradiographic axial SpA was changed from conditional to strong.

New questions on the treatment of patients with stable disease were addressed in this update. Discontinuation of biologics is not recommended due to the likelihood for symptom recurrence. If tapering is considered, patients should be counseled regarding the potential for increased disease activity. Co-treatment with low-dose methotrexate is not generally recommended, but ongoing studies will shed further light on this question. Switching to a biosimilar during the course of treatment with TNFi is also not recommended, echoing the concerns previously expressed by the ACR (52).

Imaging remains a central tool in the diagnosis of axial SpA, but its role in monitoring patients is less well-defined. Spine and/or pelvis MRI could aid in the evaluation of patients in whom the degree of active inflammation is uncertain, and especially in those for whom the findings would change management. MRI is not recommended to seek subclinical inflammation in patients with stable disease (as defined in Table 1). However, MRI could be considered in circumstances where it may inform shared decision-making. We recommend against obtaining spine radiographs on scheduled intervals to monitor progression. This practice entails radiation exposure and would not alter treatment in most cases.

We used the GRADE method to develop these treatment recommendations in a way that was transparent, systematic, and explicit, and that was informed by the medical evidence as well as patient preferences. The major limitation of these guidelines is the very low quality of evidence for many recommendations, which necessitated reliance on the clinical expertise of the panel. For nonradiographic axial SpA, most recommendations were based on extrapolation of results from studies in AS. We tried to identify the most common and consequential treatment questions, so that the recommendations would be useful in guiding clinical decision-making. The low quality of evidence for many questions is an indication that research has not yet tackled many of the most important treatment questions. As more treatment options become available, this problem will grow. Importantly, failure to recommend a particular medication does not imply that it is contraindicated. Key evidence gaps include the comparative effectiveness and safety of different biologics, the optimal sequencing of treatments, and the role of NSAIDs.

This update addressed only a subset of treatment questions. The 2015 recommendations that were not reexamined are to be considered extant. Recommendations are meant to describe the approach to treatment of the typical patient and cannot anticipate all possible clinical scenarios. Application of these recommendations must be individualized, and requires

careful assessment, sound clinical judgment of each patient's circumstances, and consideration of a patient's preferences.

ACKNOWLEDGMENTS

We thank Cassie Shafer and Elin Aslanyan of the SAA for their partnership on this project. We thank SPARTAN for its partnership on this project. We thank our patient representatives for adding valuable perspectives. We thank the ACR staff, including Ms Regina Parker for assistance in organizing the face-to-face meeting and coordinating the administrative aspects of the project, and Ms Robin Lane for assistance in manuscript preparation. We thank Ms Janet Waters for help in developing the literature search strategy and performing the literature search and updates, and Ms Janet Joyce for peer-reviewing the literature search strategy.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Dr. Ward had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

BSR and BHPR guideline for the treatment of axial spondyloarthritis (including ankylosing spondylitis) with biologics

Louise Hamilton[1], Nick Barkham[2], Ashok Bhalla[3], Robin Brittain[4], Debbie Cook[5], Gareth Jones[6], Kirsten Mackay[7], David Marshall[8], Helena Marzo-Ortega[9], Daniel Murphy[10], Claire Riddell[11], Raj Sengupta[3], Stefan Siebert[12], Liz Van Rossen[13] and Karl Gaffney[1], on behalf of the BSR and BHPR Standards, Guidelines and Audit Working Group

Key words: ankylosing spondylitis, axial spondyloarthritis, anti-TNF, biologic, guideline, treatment

Executive Summary

Scope and purpose

Axial SpA (axSpA) is a chronic inflammatory condition predominantly involving the spine and sacroiliac joints (SIJ), with or without extra-spinal manifestations including peripheral arthritis, enthesitis, iritis, psoriasis and IBD. Individuals with axSpA experience significant pain, stiffness and lack of function that translates into important health care costs and increased mortality.

AxSpA can be classified into two subgroups: radiographic axSpA, commonly referred to as AS, and non-radiographic axSpA (nr-axSpA). The primary difference between these two subgroups is the presence or absence of defined structural changes in the SIJ as detected on plain radiography. Although patients with nr-axSpA do not fulfil the modified New York criteria for AS [1], their burden of disease is similar [2] and they may derive as much benefit from treatment as patients with established AS.

This revision of the 2005 BSR guidelines [3] provides evidence-based guidance for UK clinicians prescribing biologic drugs for adult patients across the spectrum of axSpA. This includes the criteria for starting treatment, the

NICE has accredited the process used by the BSR to produce its treatment of axial spondyloarthritis with biologics guidance. Accreditation is valid for 5 years from 10 June 2013. More information on accreditation can be viewed at www.nice.org.uk/accreditation. For full details on our accreditation visit: www.nice.org.uk/accreditation.

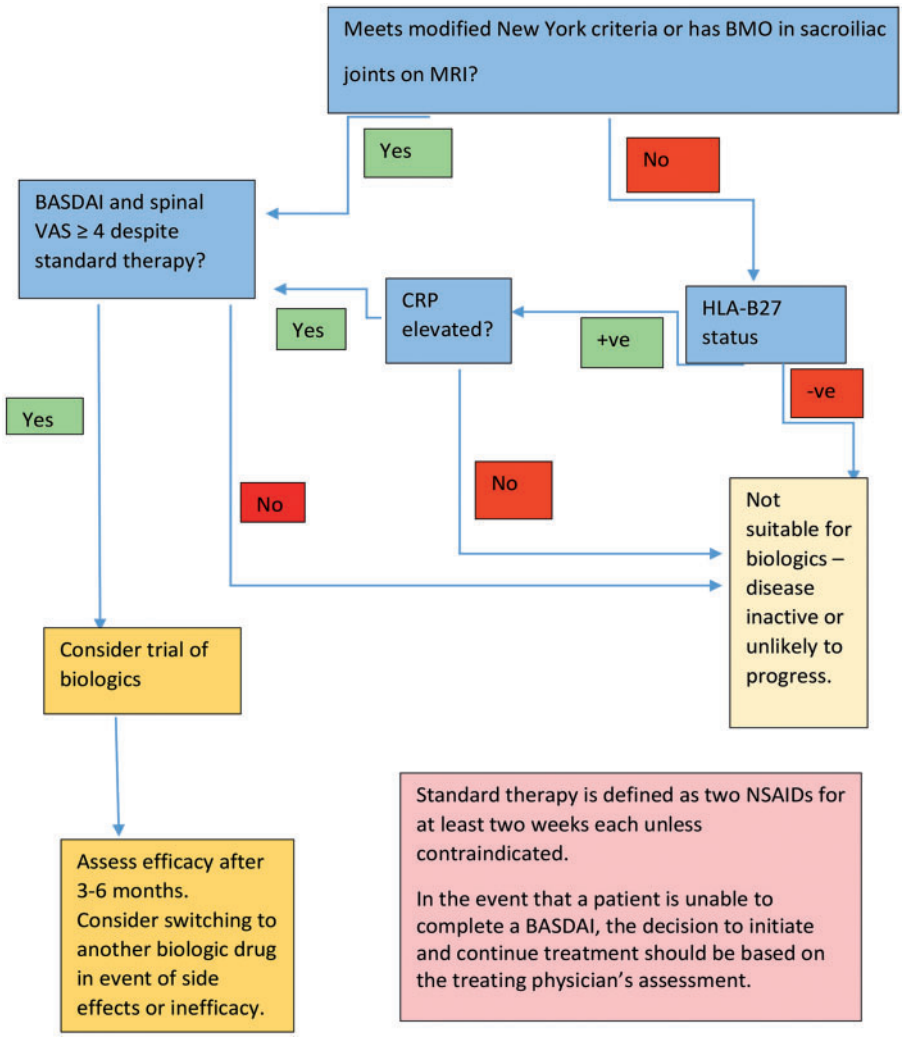
FIG. 1 Treatment algorithm for biologic therapy in axSpA



Meets modified New York criteria or has BMO in sacroiliac joints on MRI?
Yes
No
BASDAI and spinal VAS ≥ 4 despite standard therapy?
CRP elevated?
Yes
HLA-B27 status
+ve
-ve
Yes
No
No
Not suitable for biologics – disease inactive or unlikely to progress.
Consider trial of biologics
Assess efficacy after 3-6 months. Consider switching to another biologic drug in event of side effects or inefficacy.
Standard therapy is defined as two NSAIDs for at least two weeks each unless contraindicated.
In the event that a patient is unable to complete a BASDAI, the decision to initiate and continue treatment should be based on the treating physician's assessment.

BMO: bone marrow oedema; VAS: visual analogue scale.

choice of drug and assessing response to treatment. Peripheral spondyloarthritis and juvenile SpA are outside the scope of these guidelines, and readers are referred to the BSR 2012 guidelines for the management of PsA [4].

Key recommendations

These recommendations are summarized in a treatment algorithm (Fig. 1). Accompanying descriptions of evidence and full recommendations are given in the full guideline, provided as supplementary data, available at *Rheumatology* Online.

The effectiveness of biologics in axSpA

(i) Anti-TNF therapy is effective at reducing disease activity and spinal pain in axSpA. While short-term MRI data support the efficacy of anti-TNF therapy in treating inflammatory SIJ and spinal lesions in axSpA, evidence for anti-TNF therapy on radiographic disease progression is currently limited [level of evidence (LOE) 1+; strength of recommendation A; consensus score 9.6].

(ii) Currently there is insufficient evidence to recommend the use of other biologic agents in axSpA (LOE 1+; strength of recommendation B; consensus score 9.3).

Initiating treatment

(i) Patients should be considered for anti-TNF therapy if they have active axSpA (LOE 1+; strength of recommendation B; consensus score 9.6).

(ii) Active disease is defined as a BASDAI and spinal pain visual analogue scale (VAS) score $\geqslant 4$ despite standard therapy (LOE 1+; strength of recommendation B; consensus score 8.5).

(iii) The BASDAI should be measured on two occasions at least 4 weeks apart. Current National Institute for Health and Care Excellence guidelines require patients to have active spinal disease on two separate

Downloaded from https://academic.oup.com/rheumatology/article/56/2/313/2631549 by guest on 03 February 2023

occasions 12 weeks apart, with the aim of avoiding the overtreatment of patients with a short-lived flare of disease. However, as flares in AS last for an average of 2–3 weeks [5], an interval of 4 weeks between scores is sufficient and should not delay treatment unduly (LOE 2+; strength of recommendation C; consensus score 7.2).

(iv) Patients with active disease who do not meet modified New York criteria for AS should also have had a positive MRI and/or raised CRP. Prescribers should be confident that worsening symptoms, radiological changes and raised inflammatory markers are due to axSpA and not to other pathology such as malignancy or infection. Discussion with an axSpA specialist should be considered before starting treatment in a patient with nr-axSpA and no SIJ bone marrow oedema on MRI (LOE 1+; strength of recommendation B; consensus score 9.3).

Choice of Drug

(i) Extra-articular manifestations and patient choice should be considered when selecting an anti-TNF agent. In the absence of head-to-head studies, systematic reviews have shown no statistical difference in efficacy between infliximab, golimumab, etanercept and adalimumab in the treatment of AS (certolizumab data were not included in these comparative reviews, but its efficacy has been established in clinical trials). There are insufficient data to comment on relative efficacy in nr-axSpA. However, not all biologics are licensed for or effective in the treatment of extra-articular disease, so drug choice should take into account co-morbidities and the preferred route and frequency of administration (LOE 4; strength of recommendation D; consensus score 8.9).

Assessing Response

(i) Initial efficacy response should be assessed following 3–6 months of therapy and responders should then be reassessed every 6 months (LOE 2+; strength of recommendation D; consensus score 8.6).

(ii) Response is defined as a reduction in the BASDAI and spinal pain VAS of $\geqslant 2$ U from baseline (LOE 1+; strength of recommendation B; consensus score 8.3).

(iii) If, because of cognitive or communication difficulties, the BASDAI cannot be used to monitor disease activity, the decision to initiate and continue therapy should be based on the treating clinician's assessment of disease activity (LOE 4; strength of recommendation D; consensus score 9.9).

Withdrawal of Therapy

(i) In the absence of an initial clinical response by 6 months, or failure to maintain response at two consecutive assessments, withdrawal of that anti-TNF agent should be considered (LOE 4; strength of recommendation D; consensus score 9.4).

(ii) There is no evidence to support the withdrawal of anti-TNF therapy in treatment responders (LOE 2+; strength of recommendation B; consensus score 9).

Switching

(i) In the event of anti-TNF failure due to inefficacy or adverse events, an alternative anti-TNF agent should be offered if clinically appropriate (LOE 2+; strength of recommendation C; consensus score 9.7).

Safety

The safety of anti-TNF therapies in axSpA is comparable to other inflammatory joint diseases such as RA. There is little evidence to suggest that safety issues differ hugely with different disease groups, and the 2010 British Society for Rheumatology (BSR) guidelines on the safety of anti-TNF therapies in RA are applicable in axSpA [6].

Funding: No specific funding was received from any bodies in the public, commercial or not-for-profit sectors to carry out the work described in this summary.

Disclosure statement: L.H. has received unit funding from AbbVie, MSD, Pfizer and UCB, was sponsored to attend a meeting by MSD and has received a research grant from Pfizer. G.J. has received unit funding from Pfizer and AbbVie and an honorarium from AbbVie. D.Mu. was sponsored to attend a meeting by MSD, has received honoraria from UCB and AbbVie and sits on an advisory board for AbbVie. Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide guidance for particular patterns of practice and not to dictate the care of a particular patient. The ACR considers adherence to the recommendations within this guideline to be voluntary, with the ultimate determination regarding their application to be made by the health care provider in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed and endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. ACR recommendations are not intended to dictate payment or insurance decisions. These recommendations cannot adequately convey all uncertainties and nuances of patient care.

The American College of Rheumatology is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To develop an evidence-based guideline for the pharmacologic and nonpharmacologic treatment of psoriatic arthritis (PsA), as a collaboration between the American College of Rheumatology (ACR) and the National Psoriasis Foundation (NPF).

Methods. We identified critical outcomes in PsA and clinically relevant PICO (population/intervention/comparator/outcomes) questions. A Literature Review Team performed a systematic literature review to summarize evidence supporting the benefits and harms of available pharmacologic and nonpharmacologic therapies for PsA. GRADE (Grading of Recommendations Assessment, Development and Evaluation) methodology was used to rate the quality of the evidence. A voting panel, including rheumatologists, dermatologists, other health professionals, and patients, achieved consensus on the direction and the strength of the recommendations.

Results. The guideline covers the management of active PsA in patients who are treatment-naive and those who continue to have active PsA despite treatment, and addresses the use of oral small molecules, tumor necrosis factor inhibitors, interleukin-12/23 inhibitors (IL-12/23i), IL-17 inhibitors, CTLA4-Ig (abatacept), and a JAK inhibitor (tofacitinib). We also developed recommendations for psoriatic spondylitis, predominant enthesitis, and treatment in the presence of concomitant inflammatory bowel disease, diabetes, or serious infections. We formulated recommendations for a treat-to-target strategy, vaccinations, and nonpharmacologic therapies. Six percent of the recommendations were strong and 94% conditional, indicating the importance of active discussion between the health care provider and the patient to choose the optimal treatment.

Conclusion. The 2018 ACR/NPF PsA guideline serves as a tool for health care providers and patients in the selection of appropriate therapy in common clinical scenarios. Best treatment decisions consider each individual patient situation. The guideline is not meant to be proscriptive and should not be used to limit treatment options for patients with PsA.

INTRODUCTION

Psoriatic arthritis (PsA) is a chronic inflammatory musculoskeletal disease associated with psoriasis, manifesting most commonly with peripheral arthritis, dactylitis, enthesitis, and spondylitis. Nail lesions, including pitting and onycholysis, occur in ~80–90% of patients with PsA. The incidence of PsA is ~6 per 100,000 per year, and the prevalence is ~1–2 per 1,000 in the general population (1). The annual incidence of PsA in patients with psoriasis is 2.7% (2), and the reported prevalence of PsA among patients with psoriasis has varied between 6% and 41% (1). In the majority of patients the skin symptoms develop first, followed by the arthritis; however, in some patients the skin and joint symptoms present at the same time, and in 10–15% the arthritis presents first (2).

PsA affects men and women equally. The distribution of the peripheral arthritis varies from asymmetric oligoarthritis (involving ≤4 joints) to symmetric polyarthritis (involving ≥5 joints). Distal interphalangeal joints are commonly affected and, in some patients, are the only affected joints. Axial disease, when present, usually occurs together with peripheral arthritis. Some patients present with rapidly progressive and destructive PsA–arthritis mutilans. PsA is associated with an adverse impact on health-related quality of life (3–5) and high health care costs and utilization (6,7). Greater disease activity is associated with progressive joint damage and higher mortality (8–11). Early identification of PsA and early initiation of therapy are important for improving long-term outcomes (12).

Both nonpharmacologic and pharmacologic treatment can ameliorate PsA symptoms and can occasionally result

Submitted for publication December 12, 2017; accepted in revised form September 11, 2018.

in disease remission (Figure 1). Clinicians and patients can now choose from a wide variety of pharmacologic therapies, including symptomatic treatments such as nonsteroidal anti-inflammatory drugs (NSAIDs) and intraarticular injections, as well as immunomodulatory therapies.

The presentation of PsA is heterogeneous, and health care providers frequently face challenges when considering the various treatment options. Our objective was to develop evidence-based treatment recommendations for the management of active PsA in adults, using pharmacologic and nonpharmacologic therapies. These PsA treatment recommendations can help guide both clinicians and patients to arrive at optimal management decisions.

METHODS

Methodology overview. This guideline followed the American College of Rheumatology (ACR) guideline development process (http://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines). This process includes using the GRADE (Grading of Recommendations Assessment, Development and Evaluation) methodology (13–15) (www.gradeworkinggroup.org) to rate the quality of the available evidence and to develop the recommendations. ACR policy guided disclosures and the management of conflicts of interest. The full methods are presented in detail in Supplementary Appendix 1, on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.40726/abstract.

This work involved 4 teams selected by the ACR Quality of Care Committee after reviewing individual and group volunteer applications in response to an open request for proposals announcement: 1) a Core Leadership Team, which supervised and coordinated the project and drafted the clinical questions and manuscript; 2) a Literature Review Team, which completed the literature search and abstraction; 3) an Expert Panel, composed of patients, patient advocates, rheumatologists, dermatologists, 1 dermatologist-rheumatologist, and 1 rheumatology nurse practitioner, which developed the clinical questions (PICO [population/intervention/comparator/outcomes] questions) and decided on the scope of the guideline project; and 4) a Voting Panel, which included rheumatologists, 1 dermatologist, 1 dermatologist-rheumatologist, 1 rheumatology physician assistant, and 2 patients (1 of whom was also a physical therapist), who provided input from the patient perspective and voted on the recommendations. Additionally, a Patient Panel consisting of 9 adults with PsA reviewed the evidence and provided input on their values and preferences, which was reviewed before discussion of each section of PsA management (e.g., treatment-naive, treated, comorbidities), and was incorporated into discussions and formulation of recommendations. Supplementary Appendix 2 (http://onlinelibrary.wiley.com/doi/10.1002/art.40726/abstract) presents rosters of the team and panel members. In accordance with ACR policy, the principal investigator and the leader of the literature review team were free of conflicts, and within each team, >50% of the members were free of conflicts.

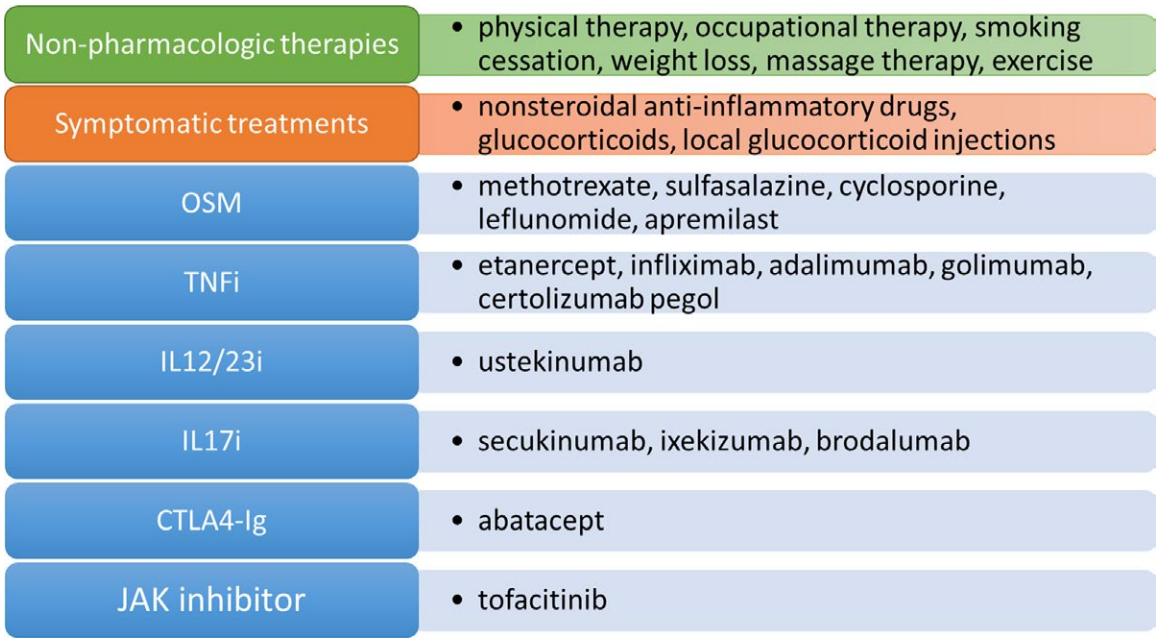

Figure 1. Pharmacologic, nonpharmacologic, and symptomatic therapies for psoriatic arthritis. Pharmacologic therapies are displayed in the blue boxes and include oral small molecules (OSMs), tumor necrosis factor inhibitor (TNFi) biologics, interleukin-17 inhibitor (IL-17i) biologics, an IL-12/23i biologic, CTLA4-immunoglobulin, and a JAK inhibitor. While there are numerous nonpharmacologic therapies available, 6 of these are addressed in this guideline. Symptomatic therapies include nonsteroidal antiinflammatory drugs, systemic glucocorticoids, and local glucocorticoid injections. Systemic glucocorticoids or local injections are not addressed in this guideline.

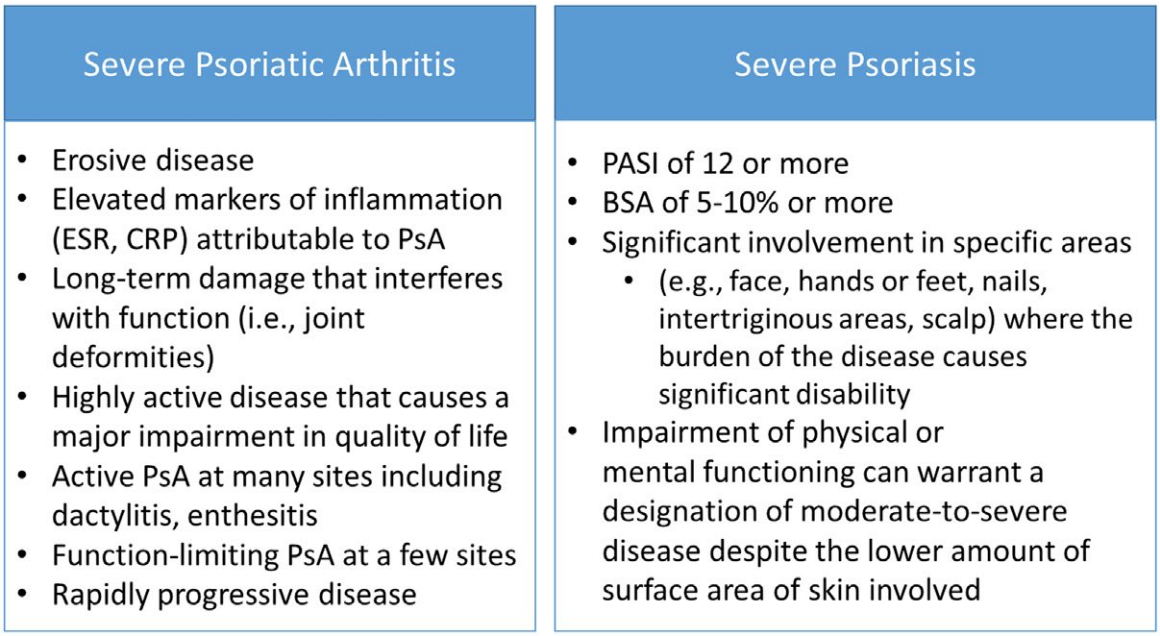
Framework for the PsA guideline development and scope of the guideline. Because there are numerous topics within PsA that could be addressed, at the beginning of the process the guideline panels made several decisions regarding the focus of this guideline and how to define aspects of the disease (e.g., active disease). At an initial scoping meeting, the Voting Panel and Expert Panel agreed that the project would include the management of patients with *active* PsA, defined as symptoms at an unacceptably bothersome level as reported by the patient and judged by the examining health care provider to be due to PsA based on the presence of at least 1 of the following: actively inflamed joints, dactylitis, enthesitis, axial disease, active skin and/or nail involvement, and/or extraarticular manifestations such as uveitis or inflammatory bowel disease (IBD). The health care provider may, in deciding if symptoms are due to active PsA, consider information beyond the core information from the history and physical examination, such as inflammation markers (C-reactive protein [CRP] or erythrocyte sedimentation rate [ESR]) and imaging results. At the scoping meeting, the panels decided that the guideline would address both pharmacologic and nonpharmacologic therapies for the treatment of PsA. We examined evidence regarding vaccinations, treatment in the presence of common comorbidities, and implementing a treat-to-target strategy.

In addressing pharmacologic therapies, we focused on immunomodulatory agents for long-term management rather than addressing acute symptom management (i.e., through intraarticular injections and the use of systemic glucocorticoids). Tofacitinib and ixekizumab were submitted for review and potential approval by the US Food and Drug Administration (FDA) at the time of formulation of this guideline (16,17) and for this reason, these drugs were addressed in the guideline. Both drugs have been approved for PsA since then (18,19). Tofacitinib is not included within the oral small molecules (OSM) category since its benefit/risk profile differs from that of the rest of the OSMs, especially with regard to risks (20–22), and consistent with its being considered separately in other treatment guidelines (23,24). Additionally, the panel addressed alternatives in patient subpopulations (e.g., patients with predominant enthesitis, axial disease, dactylitis, comorbidities), and greater versus lesser disease severity.

There are currently no widely agreed-upon definitions of disease severity in PsA or psoriasis. Thus, health care providers and patients should judge PsA and psoriasis severity on a case-by-case basis. For the purpose of these recommendations, severity includes not only the level of disease activity at a given time point, but also the presence or absence of poor prognostic factors and long-term damage. Examples of severe PsA disease include the presence of 1 or more of the following: a poor prognostic factor (erosive disease, dactylitis, elevated levels of inflammation markers such as ESR and CRP attributable to PsA), long-term damage that interferes with function (e.g., joint deformities), highly active disease that causes a major impairment in quality of life (i.e., active psoriatic inflammatory disease at many sites [including dactylitis, enthesitis] or function-limiting inflammatory disease at few sites), and rapidly progressive disease (Figure 2). In clinical trials, severe psoriasis has been defined as a Psoriasis Area and Severity Index (PASI) (25) score of ≥12 and a body surface area score of ≥10. However, because it is cumbersome, physicians seldom use the PASI in clinical practice. Examples of definitions of severe PsA and severe psoriasis are shown in Figure 2. Finally, because the National Psoriasis Foundation (NPF) and American Academy of Dermatology are concurrently developing psoriasis treatment guidelines, the treatment of skin psoriasis separately from the inflammatory arthritis was not included in the current ACR/NPF PsA guideline.

Systematic synthesis of the literature. Systematic searches of the published English-language literature included Ovid Medline, PubMed, Embase, and the Cochrane Library (including Cochrane Database of Systematic Reviews, Database of Abstracts of Reviews of Effects, Cochrane Central Register of Controlled Trials, and Health Technology Assessments) from the beginning of each database through November 15, 2016 (Supplementary Appendix 3, on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.40726/abstract); we conducted updated searches on May 2, 2017 and again on March 8, 2018. DistillerSR software (https://distillercer.com/products/distillersr-systematic-reviewsoftware/) (Supplementary Appendix 4; http://onlinelibrary.wiley.com/doi/10.1002/art.40726/abstract) was used to facilitate duplicate screening of literature search results. Reviewers entered extracted data into RevMan software (http://tech.cochrane.org/revman), and evaluated the risk of bias in primary studies using the Cochrane risk of bias tool (http://handbook.cochrane.org/). We exported RevMan files into GRADEpro software to formulate a GRADE summary of findings table (Supplementary Appendix 5; http://onlinelibrary.wiley.com/doi/10.1002/art.40726/abstract) for each PICO question (26). Additionally, a network meta-analysis was performed when sufficient studies were available. GRADE criteria provided the framework for judging the overall quality of evidence (13).

The panels chose the critical outcomes for all comparisons at the initial scoping; these included the American College of Rheumatology 20% response criteria (ACR20) (the primary outcome for most PsA clinical trials), the Health Assessment Questionnaire disability index (a measure of physical function), the PASI 75% response criteria (PASI75) (a measure of skin psoriasis improvement), and serious infections. Both the ACR20 and the PASI75 are accepted outcome measures specified by regulatory agencies, including the US FDA, for the approval of treatments for PsA (27). Serious infections are among the issues of greatest



Severe Psoriatic Arthritis
• Erosive disease
• Elevated markers of inflammation (ESR, CRP) attributable to PsA
• Long-term damage that interferes with function (i.e., joint deformities)
• Highly active disease that causes a major impairment in quality of life
• Active PsA at many sites including dactylitis, enthesitis
• Function-limiting PsA at a few sites
• Rapidly progressive disease
Severe Psoriasis
• PASI of 12 or more
• BSA of 5-10% or more
• Significant involvement in specific areas
• (e.g., face, hands or feet, nails, intertriginous areas, scalp) where the burden of the disease causes significant disability
• Impairment of physical or mental functioning can warrant a designation of moderate-to-severe disease despite the lower amount of surface area of skin involved

Figure 2. Examples of "severe" psoriatic arthritis (PsA) and psoriasis. The guideline development group defined severe PsA and psoriasis as the presence of 1 or more of the items listed. This is not a formal definition. There have been many definitions of severe psoriasis used over time—the items here are adapted from the 2007 National Psoriasis Foundation expert consensus statement for moderate-to-severe psoriasis (68). In clinical trials, severe psoriasis has been defined as a Psoriasis Area and Severity Index (PASI) score of ≥12 and a body surface area (BSA) score of ≥10 (25). ESR = erythrocyte sedimentation rate; CRP = C-reactive protein.

concern for patients and physicians when selecting among therapies. Other specific harms (e.g., liver toxicity with methotrexate [MTX]) were included as critical outcomes for individual comparisons. We included other outcomes, such as total infections (regardless of severity), when appropriate.

Moving from evidence to recommendations. GRADE methodology specifies that panels make recommendations based on the balance of benefits and harms, the quality of the evidence (i.e., confidence in effect estimates), and patients' values and preferences. Deciding on the balance between desirable and undesirable outcomes requires estimating the relative value patients place on those outcomes. When the literature provided very limited guidance, the experience of the Voting Panel members (including physicians, a rheumatology physician assistant, and the 2 patients present) in managing the relevant cases and issues became an important source of evidence. Values and preferences, crucial to all recommendations, derived from input from the members of the Patient Panel were particularly salient in such situations. GRADE methodology allows the panels the possibility of not coming to a decision, and a summary of the discussion is noted in such cases. However, during the development of this guideline, the Voting Panel came to a conclusion in each case scenario, and such a situation did not arise.

Consensus building. The Voting Panel voted on the direction and strength of the recommendation related to each PICO question. Recommendations required a 70% level of agreement, as used previously in other similar processes (28) and in the previous ACR guidelines (23,29,30); if 70% agreement was not achieved during an initial vote, the panel members held additional discussions before revoting. For all conditional recommendations, a written explanation is provided, describing the reasons for the decision and conditions under which the alternative choice may be preferable.

Moving from recommendations to practice. These recommendations are designed to help health care providers work with patients in selecting therapies. The presence or absence of concomitantly occurring conditions, such as IBD, uveitis, diabetes, and serious infections, and the knowledge of previous therapies, influence decisions regarding optimal management. In the context of PsA, the physical examination, which is also required for selecting therapy, includes assessment of the peripheral joints (including for dactylitis), the entheses, the spine, the skin, and the nails. Health care providers and patients must take into consideration all active disease domains, comorbidities, and the patient's functional status in choosing the optimal therapy for an individual at a given point in time.

RESULTS/RECOMMENDATIONS

How to interpret the recommendations

1. A *strong recommendation* means that the panel was *confident* that the desirable effects of following the recommendation outweigh the undesirable effects (or vice versa), so the course of action would apply to all or almost all patients, and only a small proportion of clinicians/patients not wanting to follow the recommendation. We use the phrase "*should use*" or "*should be used*" for strong recommendations.
2. A *conditional recommendation* means that the panel believed the desirable effects of following the recommendation *probably* outweigh the undesirable effects, so the course of action would apply to the majority of the patients, but a small proportion of clinicians/patients may not want to follow the recommendation. Because of this, conditional recommendations are preference sensitive and always warrant a shared decision-making approach. We use the phrase "*is recommended over*" or "*is/would be recommended*" for conditional recommendations. We specify conditions under which the less preferred drug may be used by using the phrase "*may be used*" or "*may consider*" or "*Y (less preferred drug) may be used instead of X (preferred drug)*" or "*may consider Y instead of X (preferred drug)*" for conditional recommendations.
3. Conditional recommendations were usually based on low- to very-low-quality evidence (in rare instances, moderate-quality evidence). Strong recommendations were typically based on moderate- or high-quality evidence.
4. For each recommendation, Supplementary Appendix 5 (on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.40726/abstract) provides details regarding the PICO questions and the GRADE evidence tables.
5. In each case, the Voting Panel's recommendation was based on a judgment of the most likely net benefit, i.e.,1) more benefit with the medication conditionally recommended with no difference in harms between the medications being compared (e.g., choosing a TNFi over OSMs in treatment-naive patients) or 2) less harm with the medication conditionally recommended and no difference in benefit (e.g., choosing abatacept over a TNFi in patients at risk of or with a history of previous infections, or preferring a different OSM over MTX in patients with PsA and diabetes due to an increased risk of liver toxicity in this subpopulation).
6. This is an evidence-based guideline, in that we explicitly use the best evidence available and present that in a transparent manner for the clinician reader/user (31,32). In some instances, this includes a randomized trial directly comparing the interventions under consideration. In other cases, in the absence of any published evidence, the best evidence comes from the collective experience of the Voting Panel and patient panel members, which in the GRADE system is rated as "very-low-quality" evidence.

Recommendations for pharmacologic interventions

Active PsA in treatment-naive patients (Table 1 and Figure 3). *All recommendations for treatment-naive patients with active PsA are conditional based on low- to very-low-quality evidence.*

In treatment-naive patients with active PsA, a TNFi biologic agent is recommended over an OSM as a first-line option (Table 1). OSMs may be used instead of a TNFi biologic in patients without severe PsA and without severe psoriasis (as defined in Methods and Figure 2; final determination of severity to be made by the patient and the health care provider), those who prefer an oral drug instead of parenteral therapy, or those with contraindications to TNFi treatment, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.

For treatment-naive patients with active PsA, the use of a TNFi biologic or OSM is recommended over an interleukin-17 inhibitor (IL-17i) or IL-12/23i biologic. An IL-17i or IL-12/23i biologic may be used instead of TNFi biologics in patients with severe psoriasis or contraindications to TNFi biologics, and may be used instead of OSMs in patients with severe psoriasis or severe PsA. MTX is recommended over NSAIDs in treatment-naive patients with active PsA. NSAIDs may be used instead of MTX after consideration of possible contraindications and side effect profile in patients without evidence of severe PsA or severe psoriasis and in those at risk for liver toxicity (Table 1 and Figure 3). An IL-17i biologic is recommended over an IL-12/23i biologic. IL-12/23i biologics may be used in patients who have concomitant IBD or who desire less frequent drug administration.

Active PsA despite treatment with an OSM (Table 2 and Figure 4). *All recommendations for patients with active PsA despite treatment with an OSM are conditional based on mostly low- to very-low-quality evidence and, in a few instances, moderate-quality evidence.*

In patients with active PsA despite OSM therapy, switching to a TNFi, an IL-17i, or an IL-12/23i biologic is recommended over switching to a different OSM (Table 2 and Figure 4). A different OSM may be used rather than a TNFi, IL-17i, or IL-12/23i in patients who prefer an oral medication or those without evidence of severe PsA or severe psoriasis; a differ-

Table 1. Recommendations for the initial treatment of patients with active psoriatic arthritis who are OSM- and other treatment–naive (PICOs 9–15)*

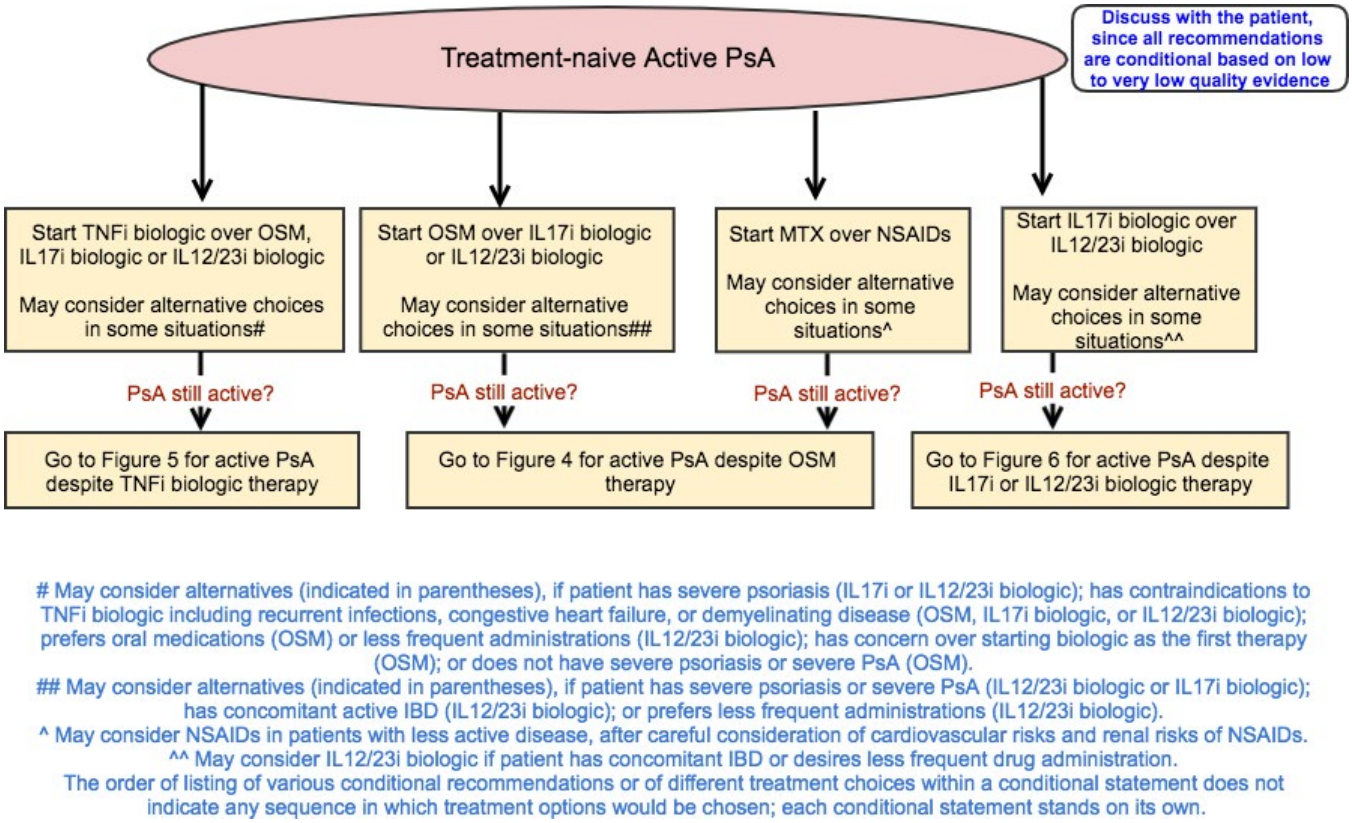
	Level of evidence (evidence [refs.] reviewed)†
In OSM- and other treatment–naive patients with active PsA,	
1. **Treat with a TNFi biologic over an OSM** (MTX, SSZ, LEF, CSA, or APR) (PICO 10a–e) **Conditional recommendation** based on low-quality evidence; may consider an OSM if the patient does not have severe PsA,‡ does not have severe psoriasis,§ prefers oral therapy, has concern over starting a biologic as the first therapy, or has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.	Low (53–66)
2. **Treat with a TNFi biologic over an IL-17i biologic** (PICO 14) **Conditional recommendation** based on very-low-quality evidence; may consider an IL-17i biologic if the patient has severe psoriasis or has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.	Very low
3. **Treat with a TNFi biologic over an IL-12/23i biologic** (PICO 13) **Conditional recommendation** based on very-low-quality evidence; may consider an IL-12/23i biologic if the patient has severe psoriasis, prefers less frequent drug administration, or has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.	Very low
4. **Treat with an OSM over an IL-17i biologic** (PICO 12) **Conditional recommendation** based on very-low-quality evidence; may consider an IL-17i biologic if the patient has severe psoriasis and/or severe PsA.	Very low
5. **Treat with an OSM over an IL-12/23i biologic** (PICO 11) **Conditional recommendation** based on very-low-quality evidence; may consider an IL-12/23i biologic if the patient has concomitant IBD and/or severe psoriasis and/or severe PsA or prefers less frequent drug administration.	Very low
6. **Treat with MTX over NSAIDs** (PICO 9) **Conditional recommendation** based on very-low-quality evidence; may consider NSAIDs before starting MTX in patients with less active disease, after careful consideration of cardiovascular risks and renal risks of NSAIDs.	Very low (67)
7. **Treat with an IL-17i biologic over an IL-12/23i biologic** (PICO 15) **Conditional recommendation** based on very-low-quality evidence; may consider an IL-12/23i biologic if the patient has concomitant IBD or prefers less frequent drug administration.	Very low

***** Active psoriatic arthritis (PsA) is defined as disease causing symptoms at an unacceptably bothersome level as reported by the patient, and judged by the examining clinician to be *due to PsA* based on ≥1 of the following: swollen joints, tender joints, dactylitis, enthesitis, axial disease, active skin and/or nail involvement, and extraarticular inflammatory manifestations such as uveitis or inflammatory bowel disease (IBD). Oral small molecules (OSMs) are defined as methotrexate (MTX), sulfasalazine (SSZ), leflunomide (LEF), cyclosporine (CSA), or apremilast (APR) and *do not* include tofacitinib, which was handled separately since its efficacy/safety profile is much different from that of other OSMs listed above. OSM- and other treatment–naive is defined as naive to treatment with OSMs, tumor necrosis factor inhibitors (TNFi,) interleukin-17 inhibitors (IL-17i), and IL-12/23i; patients may have received nonsteroidal antiinflammatory drugs (NSAIDs), glucocorticoids, and/or other pharmacologic and nonpharmacologic interventions.

† When there were no published studies, we relied on the clinical experience of the panelists, which was designated very-low-quality evidence.

‡ Because there are currently no widely agreed-upon definitions of disease severity, PsA severity should be established by the health care provider and patient on a case-by-case basis. For the purposes of these recommendations, severity is considered a broader concept than disease activity in that it encompasses the level of disease activity at a given time point, as well as the presence of poor prognostic factors and long-term damage. Examples of severe PsA disease include the presence of ≥1 of the following: a poor prognostic factor (erosive disease, elevated levels of inflammation markers such as C-reactive protein or erythrocyte sedimentation rate attributable to PsA), long-term damage that interferes with function (e.g., joint deformities, vision loss), highly active disease that causes major impairment in quality of life (i.e., active psoriatic inflammatory disease at many sites [including dactylitis, enthesitis] or function-limiting inflammatory disease at few sites), and rapidly progressive disease.

§ Because there are currently no widely agreed-upon definitions of disease severity, psoriasis severity should be established by the health care provider and patient on a case-by-case basis. In clinical trials, severe psoriasis has been defined as a Psoriasis Area and Severity Index (PASI) score (25) of ≥12 and a body surface area score of ≥10. In clinical practice, however, the PASI tool is not standardly utilized given its cumbersome nature. In 2007, the National Psoriasis Foundation published an expert consensus statement, which defined moderate-to-severe disease as a body surface area of ≥5% (68). In cases in which the involvement is in critical areas, such as the face, hands or feet, nails, intertriginous areas, scalp, or where the burden of the disease causes significant disability or impairment of physical or mental functioning, the disease can be severe despite the lower amount of surface area of skin involved. The need to factor in the unique circumstances of the individual patient is of critical importance, but this threshold provides some guidance in the care of patients.



Treatment-naive Active PsA
Discuss with the patient, since all recommendations are conditional based on low to very low quality evidence
Start TNFi biologic over OSM, IL17i biologic or IL12/23i biologic
May consider alternative choices in some situations#
Start OSM over IL17i biologic or IL12/23i biologic
May consider alternative choices in some situations##
Start MTX over NSAIDs
May consider alternative choices in some situations^
Start IL17i biologic over IL12/23i biologic
May consider alternative choices in some situations^^
PsA still active?
PsA still active?
PsA still active?
PsA still active?
Go to Figure 5 for active PsA despite TNFi biologic therapy
Go to Figure 4 for active PsA despite OSM therapy
Go to Figure 6 for active PsA despite IL17i or IL12/23i biologic therapy
May consider alternatives (indicated in parentheses), if patient has severe psoriasis (IL17i or IL12/23i biologic); has contraindications to TNFi biologic including recurrent infections, congestive heart failure, or demyelinating disease (OSM, IL17i biologic, or IL12/23i biologic); prefers oral medications (OSM) or less frequent administrations (IL12/23i biologic); has concern over starting biologic as the first therapy (OSM); or does not have severe psoriasis or severe PsA (OSM).
May consider alternatives (indicated in parentheses), if patient has severe psoriasis or severe PsA (IL12/23i biologic or IL17i biologic); has concomitant active IBD (IL12/23i biologic); or prefers less frequent administrations (IL12/23i biologic).
^ May consider NSAIDs in patients with less active disease, after careful consideration of cardiovascular risks and renal risks of NSAIDs.
^^ May consider IL12/23i biologic if patient has concomitant IBD or desires less frequent drug administration.
The order of listing of various conditional recommendations or of different treatment choices within a conditional statement does not indicate any sequence in which treatment options would be chosen; each conditional statement stands on its own.

Figure 3. Recommendations for the treatment of patients with active psoriatic arthritis (PsA) who are treatment-naive (no exposure to oral small molecules [OSMs] or other treatments). All recommendations are conditional based on low- to very-low-quality evidence. A conditional recommendation means that the panel believed the desirable effects of following the recommendation probably outweigh the undesirable effects, so the course of action would apply to the majority of the patients, but some may not want to follow the recommendation. Because of this, conditional recommendations are preference sensitive and always warrant a shared decision-making approach. Due to the complexity of management of active PsA, not all clinical situations and choices could be depicted in this flow chart, and therefore we show only the key recommendations. For a complete list of recommendations, please refer to the Results section of the text. For the level of evidence supporting each recommendation, see Table 1 and the related section in the Results. This figure is derived from recommendations based on PICO (population/intervention/comparator/outcomes) questions that are based on the common clinical situations. Active PsA was defined as symptoms at an unacceptably bothersome level as reported by the patient, and judged by the examining health care provider to be due to PsA based on the presence of at least 1 of the following: actively inflamed joints, dactylitis, enthesitis, axial disease, active skin and/or nail involvement, and/or extraarticular manifestations such as uveitis or inflammatory bowel disease (IBD). TNFi = tumor necrosis factor inhibitor; IL-17i = interleukin-17 inhibitor; MTX = methotrexate; NSAIDs = nonsteroidal antiinflammatory drugs.

ent OSM may be used rather than a TNFi in the presence of contraindications to TNFi biologics. A TNFi biologic is recommended over an IL-17i biologic, an IL-12/23i biologic, abatacept, or tofacitinib. An IL-17i biologic is recommended over an IL-12/23i biologic, abatacept, or tofacitinib. An IL-12/23i is recommended over abatacept or tofacitinib. In patients with contraindications to TNFi agents, an IL-12/23i, an IL-17i, abatacept, or tofacitinib may be used instead of a TNFi. In patients with severe psoriasis, an IL-12/23i or an IL-17i may be used instead of a TNFi. Tofacitinib may be used instead of a TNFi in patients preferring oral medication who do not have severe psoriasis.

Switching to another OSM is recommended over adding another OSM to the current treatment (except in the case of apremilast). Adding another OSM (except apremilast) to current treatment may be considered if the patient has exhibited partial response to the current OSM. Adding apremilast to the current OSM therapy is recommended over switching to apremilast monotherapy since most evidence for benefits of apremilast pertains to apremilast combination therapy. Switching to apremilast monotherapy may be considered instead of apremilast combination therapy if the patient has intolerable side effects with the current OSM.

Biologic monotherapy is recommended over biologic combination therapy with MTX (the most commonly used OSM in combination therapy). When switching to biologic monotherapy, stopping the OSM or tapering of the OSM are both reasonable options and depend on patient and health care provider

Table 2. Recommendations for treatment of patients with active psoriatic arthritis despite treatment with an OSM (PICOs 16–25; 67–69; 76–78)*

	Level of evidence (evidence [refs.] reviewed)†
In adult patients with active PsA despite treatment with an OSM,	
1. **Switch to a TNFi biologic over a different OSM** (PICO 23) **Conditional recommendation** based on moderate-quality evidence; may consider switching to a different OSM if the patient has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease, if the patient prefers an oral versus parenteral therapy, or in patients without evidence of severe PsA‡ or severe psoriasis.§	Moderate (62–66, 69–86)
2. **Switch to a TNFi biologic over an IL-17i biologic** (PICO 17) **Conditional recommendation** based on moderate-quality evidence; may consider an IL-17i if the patient has severe psoriasis and/or has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease, and/or a family history of demyelinating disease such as multiple sclerosis.	Moderate (62–66, 72–78, 87–97)
3. **Switch to a TNFi biologic over an IL-12/23i biologic** (PICO 16) **Conditional recommendation** based on moderate-quality evidence; may consider an IL-12/23i if the patient has severe psoriasis and/or contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease, or prefers less frequent drug administration.	Moderate (62–66, 72–78, 97–102)
4. **Switch to a TNFi biologic over abatacept** (PICO 67) **Conditional recommendation** based on low-quality evidence; may consider abatacept if the patient has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.	Low (62–66, 72–78, 103, 104)
5. **Switch to a TNFi biologic over tofacitinib** (PICO 76) **Conditional recommendation** based on low-quality evidence; may consider tofacitinib if the patient has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease, or prefers oral medication.	Low (62–66, 72–78, 105)
6. **Switch to an IL-17i over a different OSM** (PICO 25) **Conditional recommendation** based on low-quality evidence; may consider switching to a different OSM if the patient prefers an oral versus parenteral therapy or in patients without evidence of severe PsA or severe psoriasis.	Low (79–87, 89–95)
7. **Switch to an IL-17i biologic over an IL-12/23i biologic** (PICO 18) **Conditional recommendation** based on moderate-quality evidence; may consider an IL-12/23i biologic if the patient has concomitant IBD or prefers less frequent drug administration.	Moderate (87, 89–95, 98–100, 106, 107)
8. **Switch to an IL-17i biologic over abatacept** (PICO 69) **Conditional recommendation** based on low-quality evidence; may consider abatacept in patients with recurrent or serious infections.	Low (89–95, 103, 104)
9. **Switch to an IL-17i biologic over tofacitinib** (PICO 78) **Conditional recommendation** based on low-quality evidence; may consider tofacitinib if the patient prefers an oral therapy or has a history of recurrent *Candida i*nfections.	Low (89–95, 105)
10. **Switch to an IL-12/23i biologic over a different OSM** (PICO 24) **Conditional recommendation** based on low-quality evidence; may consider switching to a different OSM if the patient prefers an oral versus parenteral therapy or in patients without evidence of severe PsA or severe psoriasis.	Low (79–86, 98–100)
11. **Switch to an IL-12/23i biologic over abatacept** (PICO 68) **Conditional recommendation** based on low-quality evidence; may consider abatacept in patients with recurrent or serious infections.	Low (98–100, 103, 104)

Table 2. *(Cont'd)*

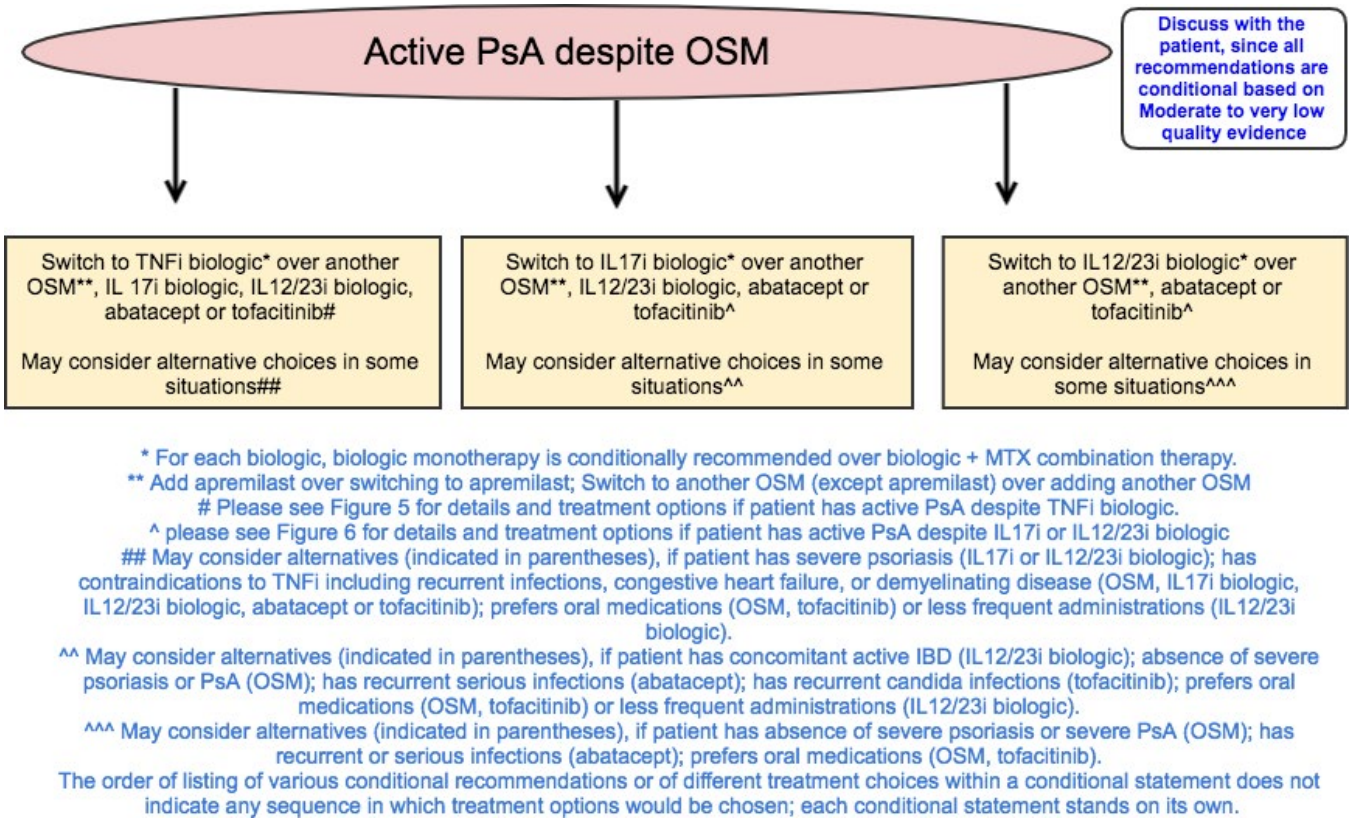
	Level of evidence (evidence [refs.] reviewed)†
12. **Switch to an IL-12/23i biologic over tofacitinib** (PICO 77) **Conditional recommendation** based on low-quality evidence; may consider tofacitinib if the patient prefers an oral therapy.	Low (98–100, 105)
13. **Add apremilast to current OSM therapy over switching to apremilast** (PICO 22b) **Conditional recommendation** based on low-quality evidence; may consider switching to apremilast if the patient has intolerable side effects with the current OSM.	Low (83, 84, 108)
14. **Switch to another OSM (except apremilast) over adding another OSM (except apremilast) to current treatment** (PICO 22a) **Conditional recommendation** based on low-quality evidence; may consider adding another OSM (except apremilast) to current treatment if the patient has demonstrated partial response to the current OSM.	Low (83, 84, 108)
15. **Switch to a TNFi biologic monotherapy over MTX and a TNFi biologic combination therapy** (PICO 19) **Conditional recommendation** based on low-quality evidence; may consider MTX and TNFi biologic combination therapy if the patient has severe skin manifestations, has had a partial response to current MTX therapy, has concomitant uveitis (since uveitis may respond to MTX therapy), and if the current TNFi biologic is infliximab or adalimumab.	Low (109–111)
16. **Switch to an IL-17i biologic monotherapy over MTX and an IL-17i biologic combination therapy** (PICO 21) **Conditional recommendation** based on very-low-quality evidence; may consider MTX and an IL-17i biologic combination therapy if the patient has severe skin manifestations, has had a partial response to current MTX therapy, or has concomitant uveitis (since uveitis may respond to MTX therapy).	Very low
17. **Switch to an IL-12/23i biologic monotherapy over MTX and an IL-12/23i biologic combination therapy** (PICO 20) **Conditional recommendation** based on very-low-quality evidence; may consider MTX and an IL-12/23i biologic combination therapy if the patient has severe skin manifestations, has had a partial response to current MTX therapy, or has concomitant uveitis (since uveitis may respond to MTX therapy).	Very low

***** Active psoriatic arthritis (PsA) is defined as disease causing symptoms at an unacceptably bothersome level as reported by the patient, and judged by the examining clinician to be *due to PsA* based on ≥1 of the following: swollen joints, tender joints, dactylitis, enthesitis, axial disease, active skin and/or nail involvement, and extraarticular inflammatory manifestations such as uveitis or inflammatory bowel disease (IBD). Oral small molecules (OSMs) are defined as methotrexate (MTX), sulfasalazine, leflunomide, cyclosporine, or apremilast and *do not* include tofacitinib, which was handled separately since its efficacy/safety profile is much different from that of other OSMs listed above. TNFi = tumor necrosis factor inhibitor; IL-17i = interleukin-17 inhibitor.

† When there were no published studies, we relied on the clinical experience of the panelists, which was designated very-low-quality evidence.

‡ Because there are currently no widely agreed-upon definitions of disease severity, PsA severity should be established by the health care provider and patient on a case-by-case basis. For the purposes of these recommendations, severity is considered a broader concept than disease activity in that it encompasses the level of disease activity at a given time point, as well as the presence of poor prognostic factors and long-term damage. Examples of severe PsA disease include the presence of ≥1 of the following: a poor prognostic factor (erosive disease, elevated levels of inflammation markers such as C-reactive protein or erythrocyte sedimentation rate attributable to PsA), long-term damage that interferes with function (e.g., joint deformities, vision loss), highly active disease that causes major impairment in quality of life (i.e., active psoriatic inflammatory disease at many sites [including dactylitis, enthesitis] or function-limiting inflammatory disease at few sites), and rapidly progressive disease.

§ Because there are currently no widely agreed-upon definitions of disease severity, psoriasis severity should be established by the health care provider and patient on a case-by-case basis. In clinical trials, severe psoriasis has been defined as a Psoriasis Area and Severity Index (PASI) score (25) of ≥12 and a body surface area score of ≥10. In clinical practice, however, the PASI tool is not standardly utilized given its cumbersome nature. In 2007, the National Psoriasis Foundation published an expert consensus statement, which defined moderate-to-severe disease as a body surface area of ≥5% (68). In cases in which the involvement is in critical areas, such as the face, hands or feet, nails, intertriginous areas, scalp, or where the burden of the disease causes significant disability or impairment of physical or mental functioning, the disease can be severe despite the lower amount of surface area of skin involved. The need to factor in the unique circumstances of the individual patient is of critical importance, but this threshold provides some guidance in the care of patients.



Active PsA despite OSM
Discuss with the patient, since all recommendations are conditional based on Moderate to very low quality evidence
Switch to TNFi biologic* over another OSM**, IL 17i biologic, IL12/23i biologic, abatacept or tofacitinib#
May consider alternative choices in some situations##
Switch to IL17i biologic* over another OSM**, IL12/23i biologic, abatacept or tofacitinib^
May consider alternative choices in some situations^^
Switch to IL12/23i biologic* over another OSM**, abatacept or tofacitinib^
May consider alternative choices in some situations^^^
* For each biologic, biologic monotherapy is conditionally recommended over biologic + MTX combination therapy.
** Add apremilast over switching to apremilast; Switch to another OSM (except apremilast) over adding another OSM
# Please see Figure 5 for details and treatment options if patient has active PsA despite TNFi biologic.
^ please see Figure 6 for details and treatment options if patient has active PsA despite IL17i or IL12/23i biologic
May consider alternatives (indicated in parentheses), if patient has severe psoriasis (IL17i or IL12/23i biologic); has contraindications to TNFi including recurrent infections, congestive heart failure, or demyelinating disease (OSM, IL17i biologic, IL12/23i biologic, abatacept or tofacitinib); prefers oral medications (OSM, tofacitinib) or less frequent administrations (IL12/23i biologic).
^^ May consider alternatives (indicated in parentheses), if patient has concomitant active IBD (IL12/23i biologic); absence of severe psoriasis or PsA (OSM); has recurrent serious infections (abatacept); has recurrent candida infections (tofacitinib); prefers oral medications (OSM, tofacitinib) or less frequent administrations (IL12/23i biologic).
^^^ May consider alternatives (indicated in parentheses), if patient has absence of severe psoriasis or severe PsA (OSM); has recurrent or serious infections (abatacept); prefers oral medications (OSM, tofacitinib).
The order of listing of various conditional recommendations or of different treatment choices within a conditional statement does not indicate any sequence in which treatment options would be chosen; each conditional statement stands on its own.

Figure 4. Recommendations for the treatment of patients with active psoriatic arthritis (PsA) despite treatment with oral small molecules (OSMs). All recommendations are conditional based on low- to very-low-quality evidence. A conditional recommendation means that the panel believed the desirable effects of following the recommendation probably outweigh the undesirable effects, so the course of action would apply to the majority of the patients, but some may not want to follow the recommendation. Because of this, conditional recommendations are preference sensitive and always warrant a shared decision-making approach. Due to the complexity of management of active PsA, not all clinical situations and choices could be depicted in this flow chart, and therefore we show only the key recommendations. For a complete list of recommendations, please refer to the Results section of the text. For the level of evidence supporting each recommendation, see Table 2 and the related section in the Results. TNFi = tumor necrosis factor inhibitor; IL-17i = interleukin-17 inhibitor; MTX = methotrexate.

preferences. A biologic agent in combination with MTX may be used instead of biologic monotherapy if the patient has severe psoriasis, has had a partial response to current MTX therapy, or has concomitant uveitis (since uveitis may respond to MTX therapy), or in patients receiving treatment with a monoclonal antibody TNFi biologic, especially infliximab and adalimumab, to potentially delay or prevent the formation of antidrug antibodies.

Active PsA despite treatment with a TNFi biologic agent as monotherapy or in combination therapy (Table 3 and Figure 5). *All recommendations for patients with active PsA despite TNFi biologic treatment are conditional based on low- to very-low-quality evidence.*

In patients with active PsA despite treatment with TNFi biologic monotherapy, switching to a different TNFi biologic monotherapy is recommended over switching to IL-12/23i biologic, an IL-17i biologic, abatacept, or tofacitinib monotherapy or adding MTX to the current TNFi biologic (Table 3 and Figure 5). An IL-12/23i biologic, IL-17i biologic, abatacept, or tofacitinib may be used instead of a different TNFi biologic monotherapy in the case of a primary TNFi biologic failure or a serious adverse event due to the TNFi biologic. An IL-17i or IL-12/23i biologic may be used instead of a different TNFi biologic, particularly in the presence of severe psoriasis. Abatacept may be used instead of a TNFi biologic in patients with recurrent or serious infections in the absence of severe psoriasis, based on indirect evidence of fewer hospitalized infections with abatacept compared to TNFi biologics in a population with rheumatoid arthritis (33). Tofacitinib may be used instead of a TNFi biologic if oral therapy is preferred by the patient.

In patients with active PsA despite treatment with TNFi biologic monotherapy, an IL-17i biologic is recommended over an IL-12/23i biologic, abatacept, or tofacitinib, and an IL-12/23i biologic is recommended over abatacept or tofacitinib. An IL-12/23i biologic may be considered instead of an IL-17i biologic if the patient has IBD or desires less frequent drug administration. Abatacept may be considered instead of an IL-17i or IL-

Table 3. Recommendations for treatment of patients with active psoriatic arthritis despite treatment with a TNFi biologic, as monotherapy or in combination with MTX (PICOs 26–35; 70–75)*

	Level of evidence (evidence [refs.] reviewed)†
In adult patients with active PsA despite treatment with a TNFi biologic monotherapy,	
1. **Switch to a different TNFi biologic over switching to an IL-17i biologic** (PICO 28) **Conditional recommendation** based on low-quality evidence; may consider an IL-17i if the patient had a primary TNFi biologic efficacy failure or a TNFi biologic–associated serious adverse event or severe psoriasis.‡	Low (72, 73, 90–93, 95)
2. **Switch to a different TNFi biologic over switching to an IL-12/23i biologic** (PICO 27) **Conditional recommendation** based on low-quality evidence; may consider an IL-12/23i if the patient had a primary TNFi biologic efficacy failure or a TNFi biologic–associated serious adverse effect or prefers less frequent drug administration.	Low (72, 73, 99, 100)
3. **Switch to a different TNFi biologic over switching to abatacept** (PICO 70) **Conditional recommendation** based on low-quality evidence; may consider abatacept if the patient had a primary TNFi biologic efficacy failure or TNFi biologic–associated serious adverse effect.	Low (72, 73, 103, 104)
4. **Switch to a different TNFi biologic over switching to tofacitinib** (PICO 73) **Conditional recommendation** based on low-quality evidence; may consider tofacitinib if the patient prefers an oral therapy or had a primary TNFi biologic efficacy failure or a TNFi biologic–associated serious adverse effect.	Low (62–66, 72–78, 105)
5. **Switch to a different TNFi biologic (with or without MTX) over adding MTX to the same TNFi biologic monotherapy** (PICO 26 and 26A) **Conditional recommendation** based on very-low-quality evidence; may consider adding MTX when patients have demonstrated partial response to the current TNFi biologic therapy, especially if the TNFi biologic is a monoclonal antibody.	Very low
6. **Switch to an IL-17i biologic over switching to an IL-12/23i biologic** (PICO 29) **Conditional recommendation** based on low-quality evidence; may consider an IL-12/23i if the patient has IBD or if the patient prefers less frequent drug administration.	Low (90–93, 95, 99, 100)
7. **Switch to an IL-17i biologic over abatacept** (PICO 72) **Conditional recommendation** based on low-quality evidence; may consider abatacept if the patient prefers IV dosing or in patients with recurrent or serious infections.	Low (90–93, 95, 103, 104, 112)
8. **Switch to an IL-17i biologic over tofacitinib** (PICO 75) **Conditional recommendation** based on low-quality evidence; may consider tofacitinib if the patient prefers an oral therapy or in patients with concomitant IBD or a history of recurrent *Candida* infections.	Low (90–93, 105)
9. **Switch to an IL-12/23i biologic over abatacept** (PICO 71) **Conditional recommendation** based on of low-quality evidence; may consider abatacept if the patient prefers IV dosing or in patients with recurrent or serious infections.	Low (99, 100, 103, 104)
10. **Switch to an IL-12/23i biologic over tofacitinib** (PICO 74) **Conditional recommendation** based on low-quality evidence; may consider tofacitinib if the patient prefers an oral therapy.	Low (98–100, 105)
11. **Switch to a different TNFi biologic monotherapy over switching to a different TNFi biologic and MTX combination therapy** (PICO 30) **Conditional recommendation** based on very-low-quality evidence; may consider switching to a TNFi biologic and MTX combination therapy if the current TNFi biologic is infliximab.	Very low
12. **Switch to an IL-17i biologic monotherapy over switching to an IL-17i biologic and MTX combination therapy** (PICO 32) **Conditional recommendation** based on very-low-quality evidence; may consider switching to an IL-17i biologic and MTX combination therapy in patients with concomitant uveitis, as uveitis may respond to MTX therapy.	Very low

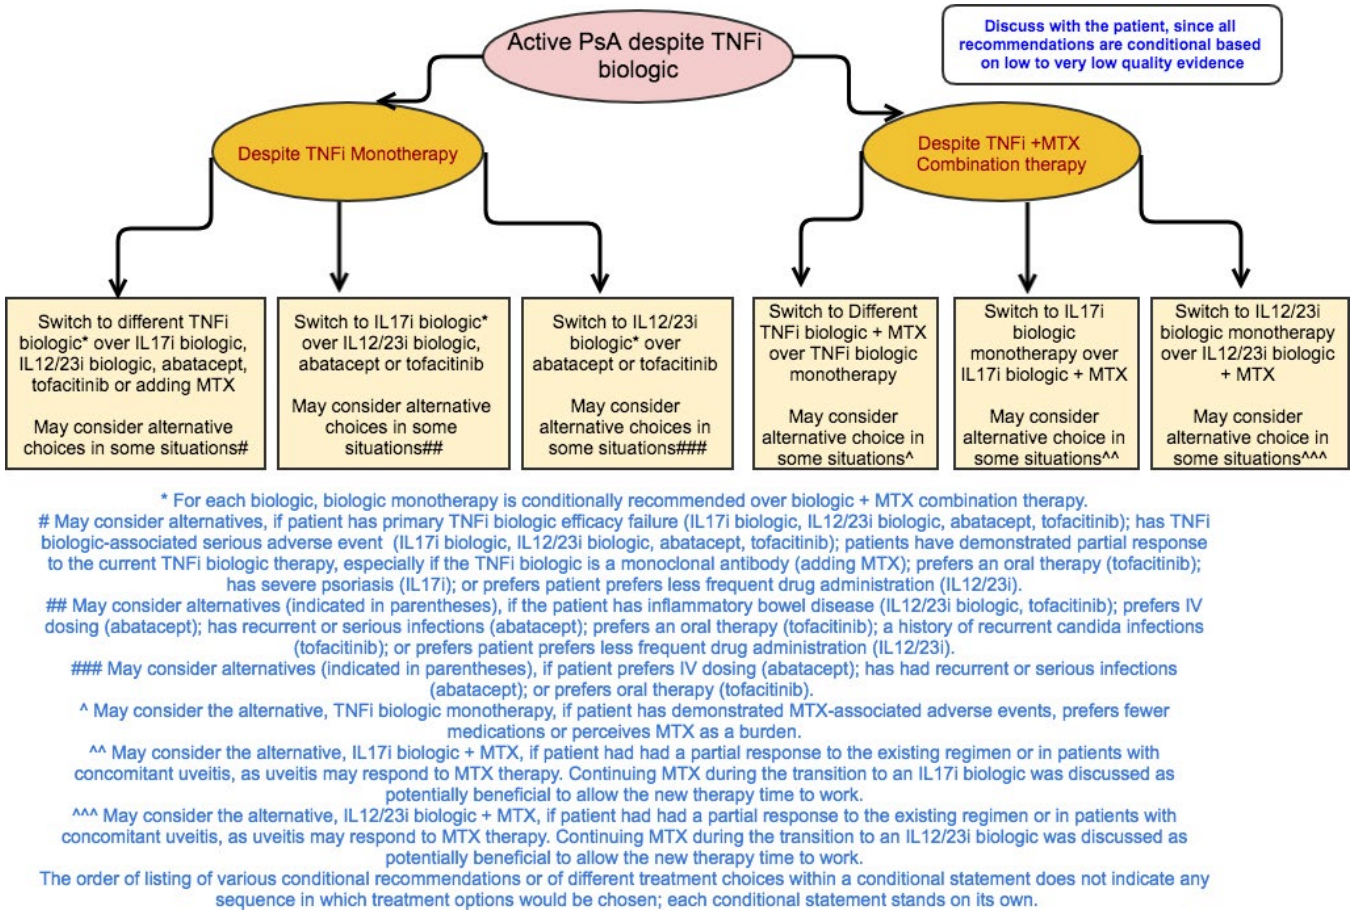
Table 3. *(Cont'd)*

	Level of evidence (evidence [refs.] reviewed)†
13. **Switch to an IL-12/23i biologic monotherapy over switching to an IL-12/23i biologic and MTX combination therapy** (PICO 31) **Conditional recommendation** based on very-low-quality evidence; may consider switching to an IL-12/23i biologic and MTX combination therapy if the patient has severe psoriasis.	Very low
In adult patients with active PsA despite treatment with a TNFi biologic and MTX combination therapy,	
14. **Switch to a different TNFi biologic + MTX over switching to a different TNFi biologic monotherapy** (PICO 33) **Conditional recommendation** based on very-low-quality evidence; may consider switching to a different TNFi biologic monotherapy if the patient has demonstrated MTX-associated adverse events, prefers to receive fewer medications, or perceives MTX as a burden.	Very low
15. **Switch to an IL-17i biologic monotherapy over an IL-17i biologic and MTX combination therapy** (PICO 35) **Conditional recommendation** based on very-low-quality evidence; may consider switching to an IL-17i biologic and MTX combination therapy if the patient had had a partial response to the existing regimen or in patients with concomitant uveitis, as uveitis may respond to MTX therapy. Continuing MTX during the transition to an IL-17i biologic was discussed as potentially beneficial to allow the new therapy time to work.	Very low
16. **Switch to IL-12/23i biologic monotherapy over IL-12/23i biologic and MTX combination therapy** (PICO 34) **Conditional recommendation** based on very-low-quality evidence; may consider switching to an IL-12/23i biologic and MTX combination therapy if the patient had had a partial response to the existing regimen or in patients with concomitant uveitis, as uveitis may respond to MTX therapy. Continuing MTX during the transition to an IL-12/23i biologic was discussed as potentially beneficial to allow the new therapy time to work.	Very low

***** Active psoriatic arthritis (PsA) is defined as disease causing symptoms at an unacceptably bothersome level as reported by the patient, and judged by the examining clinician to be *due to PsA* based on ≥1 of the following: swollen joints, tender joints, dactylitis, enthesitis, axial disease, active skin and/or nail involvement, and extraarticular inflammatory manifestations such as uveitis or inflammatory bowel disease (IBD). TNFi = tumor necrosis factor inhibitor; MTX = methotrexate; IL-17i = interleukin-17 inhibitor; IV = intravenous.
† When there were no published studies, we relied on the clinical experience of the panelists, which was designated very-low-quality evidence.
‡ Because there are currently no widely agreed-upon definitions of disease severity, psoriasis severity should be established by the health care provider and patient on a case-by-case basis. In clinical trials, severe psoriasis has been defined as a Psoriasis Area and Severity Index (PASI) score (25) of ≥12 and a body surface area score of ≥10. In clinical practice, however, the PASI tool is not standardly utilized given its cumbersome nature. In 2007, the National Psoriasis Foundation published an expert consensus statement, which defined moderate-to-severe disease as a body surface area of ≥5% (68). In cases in which the involvement is in critical areas, such as the face, hands or feet, nails, intertriginous areas, scalp, or where the burden of the disease causes significant disability or impairment of physical or mental functioning, the disease can be severe despite the lower amount of surface area of skin involved. The need to factor in the unique circumstances of the individual patient is of critical importance, but this threshold provides some guidance in the care of patients.

12/23i biologic in patients with recurrent or serious infections. Tofacitinib may be considered instead of an IL-17i biologic in patients who prefer oral therapy or have a history of recurrent or severe *Candida* infections. Tofacitinib may be considered instead of an IL-12/23i biologic in patients who prefer oral therapy. For each biologic (TNFi, IL-12/23i, or IL-17i), monotherapy is recommended over combination with MTX. Combination therapy with biologic and MTX may be used instead of biologic monotherapy in the presence of severe psoriasis, partial response to current MTX therapy, concomitant uveitis (since uveitis may respond to MTX therapy), and if the current TNFi biologic is infliximab or adalimumab (for immunogenicity prevention).

Under circumstances in which combination therapy with a TNFi biologic and MTX is used and active PsA persists, switching to a different TNFi with MTX is recommended over monotherapy with a different TNFi. Continuing MTX treatment during TNFi transition was seen as beneficial because TNFi biologics may have more sustained efficacy when used in combination with MTX, but evidence is limited (34). Monotherapy with a different TNFi biologic may be used if the patient has had MTX-associated adverse events, prefers to receive fewer medications, or perceives MTX treatment as a burden. IL-12/23i or IL-17i biologic monotherapy is recommended over either of these agents in combination with MTX. Combination therapy with an IL-17i or IL-12/23 biologic and MTX may be used instead of switching to biologic monotherapy



Active PsA despite TNFi biologic
Discuss with the patient, since all recommendations are conditional based on low to very low quality evidence
Despite TNFi Monotherapy
Despite TNFi +MTX Combination therapy
Switch to different TNFi biologic* over IL17i biologic, IL12/23i biologic, abatacept, tofacitinib or adding MTX
May consider alternative choices in some situations#
Switch to IL17i biologic* over IL12/23i biologic, abatacept or tofacitinib
May consider alternative choices in some situations##
Switch to IL12/23i biologic* over abatacept or tofacitinib
May consider alternative choices in some situations###
Switch to Different TNFi biologic + MTX over TNFi biologic monotherapy
May consider alternative choice in some situations^
Switch to IL17i biologic monotherapy over IL17i biologic + MTX
May consider alternative choice in some situations^^
Switch to IL12/23i biologic monotherapy over IL12/23i biologic + MTX
May consider alternative choice in some situations^^^
* For each biologic, biologic monotherapy is conditionally recommended over biologic + MTX combination therapy.
# May consider alternatives, if patient has primary TNFi biologic efficacy failure (IL17i biologic, IL12/23i biologic, abatacept, tofacitinib); has TNFi biologic-associated serious adverse event (IL17i biologic, IL12/23i biologic, abatacept, tofacitinib); patients have demonstrated partial response to the current TNFi biologic therapy, especially if the TNFi biologic is a monoclonal antibody (adding MTX); prefers an oral therapy (tofacitinib); has severe psoriasis (IL17i); or prefers patient prefers less frequent drug administration (IL12/23i).
May consider alternatives (indicated in parentheses), if the patient has inflammatory bowel disease (IL12/23i biologic, tofacitinib); prefers IV dosing (abatacept); has recurrent or serious infections (abatacept); prefers an oral therapy (tofacitinib); a history of recurrent candida infections (tofacitinib); or prefers patient prefers less frequent drug administration (IL12/23i).
May consider alternatives (indicated in parentheses), if patient prefers IV dosing (abatacept); has had recurrent or serious infections (abatacept); or prefers oral therapy (tofacitinib).
^ May consider the alternative, TNFi biologic monotherapy, if patient has demonstrated MTX-associated adverse events, prefers fewer medications or perceives MTX as a burden.
^^ May consider the alternative, IL17i biologic + MTX, if patient had had a partial response to the existing regimen or in patients with concomitant uveitis, as uveitis may respond to MTX therapy. Continuing MTX during the transition to an IL17i biologic was discussed as potentially beneficial to allow the new therapy time to work.
^^^ May consider the alternative, IL12/23i biologic + MTX, if patient had had a partial response to the existing regimen or in patients with concomitant uveitis, as uveitis may respond to MTX therapy. Continuing MTX during the transition to an IL12/23i biologic was discussed as potentially beneficial to allow the new therapy time to work.
The order of listing of various conditional recommendations or of different treatment choices within a conditional statement does not indicate any sequence in which treatment options would be chosen; each conditional statement stands on its own.

Figure 5. Recommendations for the treatment of patients with active psoriatic arthritis (PsA) despite treatment with a tumor necrosis factor inhibitor (TNFi) as monotherapy or as combination therapy with methotrexate (MTX). All recommendations are conditional based on low- to very-low-quality evidence. A conditional recommendation means that the panel believed the desirable effects of following the recommendation probably outweigh the undesirable effects, so the course of action would apply to the majority of the patients, but some may not want to follow the recommendation. Because of this, conditional recommendations are preference sensitive and always warrant a shared decision-making approach. Due to the complexity of management of active PsA, not all clinical situations and choices could be depicted in this flow chart, and therefore we show only the key recommendations. For a complete list of recommendations, please refer to the Results section of the text. For the level of evidence supporting each recommendation, see Table 3 and the related section in the Results. IL-17i = interleukin-17 inhibitor; IV = intravenous.

if the patient had a partial response to the existing regimen and/or has concomitant uveitis that might respond to MTX therapy.

Active PsA despite treatment with an IL-17i biologic agent as monotherapy (Table 4 and Figure 6). *All recommendations for patients with active PsA despite IL-17i biologic treatment are conditional based on very-low-quality evidence.*

In patients with active PsA despite treatment with an IL-17i biologic, switching to a TNFi biologic is recommended over switching to an IL-12/23i biologic, adding MTX to the current IL-17i biologic, or switching to a different IL-17i biologic (Table 4 and Figure 6). Switching to an IL-12/23i biologic is recommended over adding MTX to the current IL-17i biologic or switching to a different IL-17i biologic. Treatment may be switched to an IL-12/23i biologic instead of a TNFi biologic if the patient has severe psoriasis or a contraindication to TNFi biologic treatment. Another IL-17i biologic may be used instead of switching to a TNFi or IL-12/23i biologic if the patient had a secondary efficacy failure with the current IL-17i biologic, severe psoriasis, or a contraindication to TNFi treatment. MTX may be added to the current IL-17i regimen instead of switching to a TNFi or IL-12/23i biologic in patients who have had a partial response to the current IL-17i biologic.

Active PsA despite treatment with an IL-12/23i biologic agent as monotherapy (Table 4 and Figure 6). *All recommendations for patients with active PsA despite IL-12/23i biologic treatment are conditional based on very-low-quality evidence.*

In patients with active PsA despite treatment with an IL-12/23i biologic, switching to a TNFi biologic is recommended over adding MTX to the current regimen or switching to an IL-17i biologic

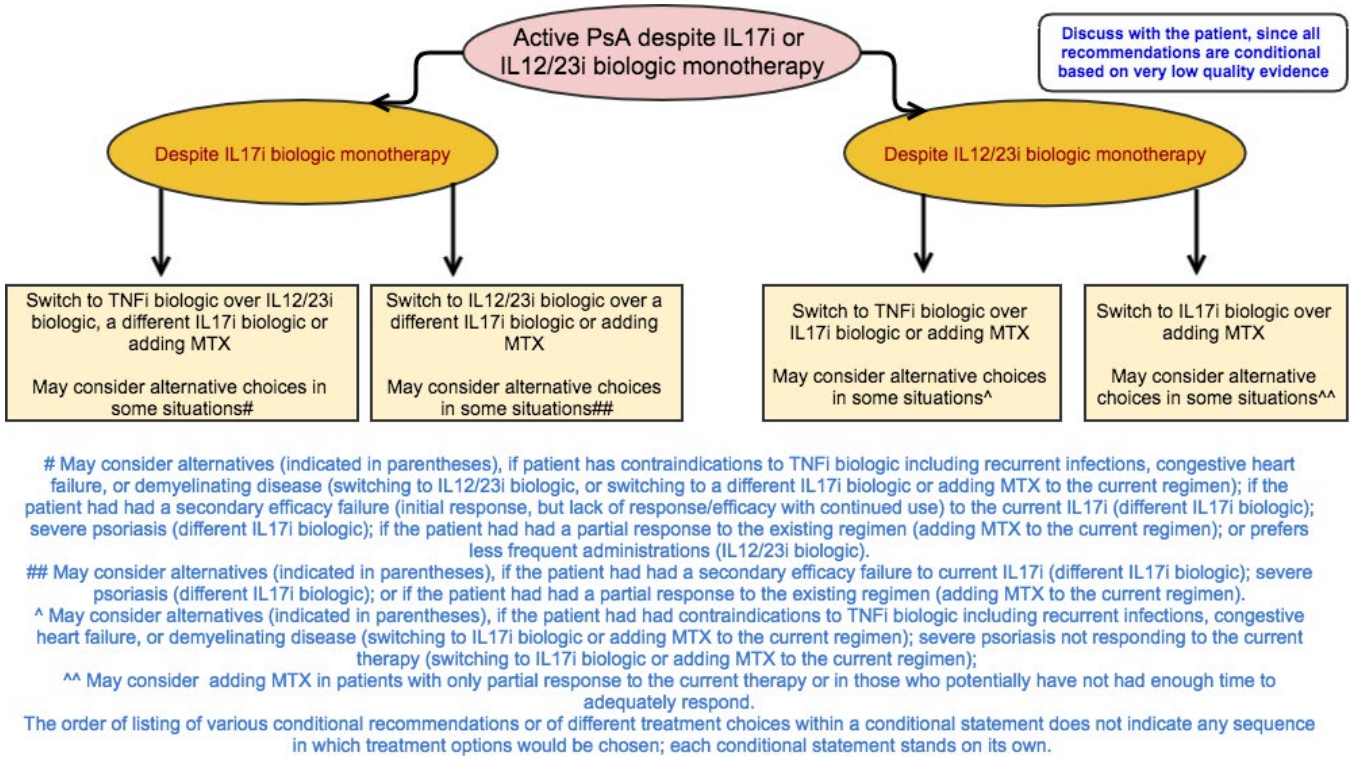
Table 4. Recommendations for treatment of patients with active psoriatic arthritis despite treatment with an IL-17i or an IL-12/23i biologic monotherapy (PICOs 36–43)*

	Level of evidence†
In adult patients with active PsA despite treatment with an IL-17i biologic monotherapy,	
1. **Switch to a TNFi biologic over switching to an IL-12/23i biologic** (PICO 39) **Conditional recommendation** based on very-low-quality-evidence; may consider switching to IL- 12/23i if the patient has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease, or prefers less frequent drug administration.	Very low
2. **Switch to a TNFi biologic over switching to a different IL-17i biologic** (PICO 42) **Conditional recommendation** based on very-low-quality evidence; may consider switching to a different IL-17i if the patient had had a secondary efficacy failure to current IL-17i, or severe psoriasis, or contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.	Very low
3. **Switch to a TNFi biologic over adding MTX to an IL-17i biologic** (PICO 41) **Conditional recommendation** based on very-low-quality evidence; may consider adding MTX to an IL-17i if the patient had had a partial response to the existing regimen or if the patient has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.	Very low
4. **Switch to an IL-12/23i biologic over switching to a different IL-17i biologic** (PICO 43) **Conditional recommendation** based on very-low-quality evidence; may consider switching to a different IL-17i if the patient had had a secondary efficacy failure to current IL-17i or severe psoriasis,‡ or if the patient has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.	Very low
5. **Switch to an IL-12/23i biologic over adding MTX to an IL-17i biologic** (PICO 40) **Conditional recommendation** based on very-low-quality evidence; may consider adding MTX to an IL-17i if the patient had had a partial response to the existing regimen.	Very low
In adult patients with active PsA despite treatment with an IL-12/23i biologic monotherapy,	
6. **Switch to a TNFi biologic over switching to an IL-17i biologic** (PICO 38) **Conditional recommendation** based on very-low-quality evidence; may consider an IL-17i if the patient has severe psoriasis or contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.	Very low
7. **Switch to a TNFi biologic over adding MTX to an IL-12/23i biologic** (PICO 36) **Conditional recommendation** based on very-low-quality evidence; may consider adding MTX in patients in whom the severe psoriasis is not responding to the current therapy, or if the patient has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.	Very low
8. **Switch to an IL-17i biologic over adding MTX to an IL-12/23i biologic** (PICO 37). **Conditional recommendation** based on very-low-quality evidence; may consider adding MTX in patients with only partial response to the current therapy or in those who potentially have not had enough time to adequately respond.	Very low

***** Active psoriatic arthritis (PsA) is defined as disease causing symptoms at an unacceptably bothersome level as reported by the patient, and judged by the examining clinician to be *due to PsA* based on ≥1 of the following: swollen joints, tender joints, dactylitis, enthesitis, axial disease, active skin and/or nail involvement, and extraarticular inflammatory manifestations such as uveitis or inflammatory bowel disease. IL-17i = interleukin-17 inhibitor; TNFi = tumor necrosis factor inhibitor; MTX = methotrexate.

† When there were no published studies—as was the case with all of the recommendations presented in this table—we relied on the clinical experience of the panelists, which was designated very-low-quality evidence.

‡ Because there are currently no widely agreed-upon definitions of disease severity, psoriasis severity should be established by the health care provider and patient on a case-by-case basis. In clinical trials, severe psoriasis has been defined as a Psoriasis Area and Severity Index (PASI) score (25) of ≥12 and a body surface area score of ≥10. In clinical practice, however, the PASI tool is not standardly utilized given its cumbersome nature. In 2007, the National Psoriasis Foundation published an expert consensus statement, which defined moderate-to-severe disease as a body surface area of ≥5% (68). In cases in which the involvement is in critical areas, such as the face, hands or feet, nails, intertriginous areas, scalp, or where the burden of the disease causes significant disability or impairment of physical or mental functioning, the disease can be severe despite the lower amount of surface area of skin involved. The need to factor in the unique circumstances of the individual patient is of critical importance, but this threshold provides some guidance in the care of patients.



Active PsA despite IL17i or IL12/23i biologic monotherapy
Discuss with the patient, since all recommendations are conditional based on very low quality evidence
Despite IL17i biologic monotherapy
Despite IL12/23i biologic monotherapy
Switch to TNFi biologic over IL12/23i biologic, a different IL17i biologic or adding MTX
May consider alternative choices in some situations#
Switch to IL12/23i biologic over a different IL17i biologic or adding MTX
May consider alternative choices in some situations##
Switch to TNFi biologic over IL17i biologic or adding MTX
May consider alternative choices in some situations^
Switch to IL17i biologic over adding MTX
May consider alternative choices in some situations^^
May consider alternatives (indicated in parentheses), if patient has contraindications to TNFi biologic including recurrent infections, congestive heart failure, or demyelinating disease (switching to IL12/23i biologic, or switching to a different IL17i biologic or adding MTX to the current regimen); if the patient had had a secondary efficacy failure (initial response, but lack of response/efficacy with continued use) to the current IL17i (different IL17i biologic); severe psoriasis (different IL17i biologic); if the patient had had a partial response to the existing regimen (adding MTX to the current regimen); or prefers less frequent administrations (IL12/23i biologic).
May consider alternatives (indicated in parentheses), if the patient had had a secondary efficacy failure to current IL17i (different IL17i biologic); severe psoriasis (different IL17i biologic); or if the patient had had a partial response to the existing regimen (adding MTX to the current regimen).
^ May consider alternatives (indicated in parentheses), if the patient had had contraindications to TNFi biologic including recurrent infections, congestive heart failure, or demyelinating disease (switching to IL17i biologic or adding MTX to the current regimen); severe psoriasis not responding to the current therapy (switching to IL17i biologic or adding MTX to the current regimen);
^^ May consider adding MTX in patients with only partial response to the current therapy or in those who potentially have not had enough time to adequately respond.
The order of listing of various conditional recommendations or of different treatment choices within a conditional statement does not indicate any sequence in which treatment options would be chosen; each conditional statement stands on its own.

Figure 6. Recommendations for the treatment of patients with active psoriatic arthritis (PsA) despite treatment with interleukin-17 inhibitor (IL-17i) or IL-12/23i biologic monotherapy. All recommendations are conditional based on low- to very-low-quality of evidence. A conditional recommendation means that the panel believed the desirable effects of following the recommendation probably outweigh the undesirable effects, so the course of action would apply to the majority of the patients, but some may not want to follow the recommendation. Because of this, conditional recommendations are preference sensitive and always warrant a shared decision-making approach. Due to the complexity of management of active PsA, not all clinical situations and choices could be depicted in this flow chart, and therefore we show only the key recommendations. For a complete list of recommendations, please refer to the Results section of the text. For the level of evidence supporting each recommendation, see Table 4 and the related section in the Results. TNFi = tumor necrosis factor inhibitor; MTX = methotrexate.

(Table 4 and Figure 6). Switching to an IL-17i biologic is recommended over adding MTX to the current therapy. Treatment may be switched to an IL-17i biologic instead of a TNFi biologic if the patient has severe psoriasis or a contraindication to TNFi biologic treatment. MTX may be added to the current IL-12/23i biologic therapy instead of switching to a TNFi or an IL-17i biologic in patients with a partial response to the current therapy; MTX may also be added to the current IL-12/23i biologic therapy instead of switching to a TNFi biologic in the presence of contraindications to TNFi biologics.

Treat-to-target (Table 5). *This recommendation for patients with active PsA is conditional based on low-quality evidence.*

In patients with active PsA, using a treat-to-target strategy is recommended over not following a-treat-to-target strategy. One may consider not using a treat-to-target strategy in patients in whom there are concerns related to increased adverse events, costs of therapy, and patient burden of medications associated with tighter control.

Active PsA with psoriatic spondylitis/axial disease despite treatment with NSAIDs (Table 5). *All recommendations for patients with active PsA with psoriatic spondylitis/axial disease despite NSAID treatment are conditional based on very-low-quality evidence.*

The ACR/Spondylitis Association of America/Spondyloarthritis Research and Treatment Network recommendations for patients with axial spondyloarthritis (35) should be followed for patients with axial PsA. OSMs are not effective for axial disease (35). In patients with active axial PsA despite NSAID treatment, a TNFi biologic is recommended over an IL-17i or IL-12/23i biologic, and an IL-17i biologic is recommended over an IL-12/23i biologic. An IL-17i biologic may be used instead of a TNFi biologic if the patient has severe psoriasis or a contraindication to TNFi biologic treatment (Table 5). We recommend *not using* an IL-12/23i biologic since 3 randomized trials of an IL-12/23i biologic (ustekinumab) in patients with axial spondyloarthritis (a related condition) were stopped because the key primary and secondary end points were not achieved (36–38); the safety profile was reportedly consistent with that observed in past ustekinumab studies.

Table 5. Recommendations for treatment of patients with active psoriatic arthritis including treat-to-target, active axial disease, enthesitis, or active inflammatory bowel disease (PICOs 44–55; 58–62)*

	Level of evidence (evidence [refs.] reviewed)†
In adult patients with active PsA,	
1. **Use a treat-to-target strategy over not following a treat-to-target strategy** (PICO 44) **Conditional recommendation** based on low-quality evidence; may consider not following a treat-to-target strategy in patients in whom higher frequency and/or severity of adverse events, higher cost of therapy, or higher patient burden of medications with tighter control are a concern.	Low (113)
In patients with active PsA with psoriatic spondylitis/axial disease despite treatment with NSAIDs,‡	
2. **Switch to a TNFi biologic over switching to an IL-17i biologic** (PICO 46) **Conditional recommendation** based on very-low-quality evidence; may consider switching to an IL-17i biologic if the patient has contraindications to TNFi biologics, congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease, or if the patient has severe psoriasis.§	Very low
3. **Switch to a TNFi biologic over switching to an IL-12/23i biologic** (PICO 45) **Conditional recommendation** based on very-low-quality evidence; switching to an IL-12/23i biologic is *not* considered since recent trials in axial SpA were stopped.	Very low
4. **Switch to an IL-17i biologic over switching to an IL-12/23i** (PICO 47) **Conditional recommendation** based on very-low-quality evidence; switching to an IL-12/23i biologic is *not* considered since recent trials in axial SpA were stopped.	Very low
In adult patients with active PsA and predominant enthesitis who are both OSM- and biologic treatment–naive,¶	
5. **Start oral NSAIDs over an OSM (specifically apremilast)** (PICO 48) **Conditional recommendation** based on very-low-quality evidence; may consider starting an OSM (specifically apremilast) if the patient has active joint disease and/or skin disease or contraindications to the use of NSAIDs, including cardiovascular disease, peptic ulcer disease, or renal disease or impairment.	Very low
6. **Start a TNFi biologic over an OSM (specifically apremilast)** (PICO 48A) **Conditional recommendation** based on very-low-quality evidence; may consider starting an OSM (specifically apremilast) if the patient prefers an oral treatment as the first therapy or the patient has contraindications to TNFi biologics, including recurrent infections, congestive heart failure, or demyelinating disease.	Very low
7. **Start tofacitinib over an OSM (specifically apremilast)** (PICO 55) **Conditional recommendation** based on very-low-quality evidence; may consider starting an OSM (specifically apremilast) if the patient has recurrent infections.	Very low
In adult patients with active PsA and predominant enthesitis despite treatment with OSM,	
8. **Switch to a TNFi biologic over an IL-17i biologic** (PICO 53) **Conditional recommendation** based on low-quality evidence; may consider switching to an IL-117i if the patient has severe psoriasis or contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.	Low (72, 73, 76, 89, 90, 92)
9. **Switch to a TNFi biologic over an IL-12/23i biologic** (PICO 52) **Conditional recommendation** based on low-quality evidence; may consider switching to an IL-12/23i if the patient has severe psoriasis or contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease, or if the patient prefers less frequent drug administration.	Low (72, 73, 76, 98, 100)
10. **Switch to a TNFi biologic over switching to another OSM** (PICO 49) **Conditional recommendation** based on low-quality evidence; may consider switching to another OSM# if the patient prefers an oral medication over an injection, or if the patient has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.	Low (72, 73, 76, 83–85)

Table 5. *(Cont'd)*

	Level of evidence (evidence [refs.] reviewed)†
11. **Switch to an IL-17i biologic over an IL-12/23i biologic** (PICO 54) **Conditional recommendation** based on low-quality evidence; may consider switching to an IL-12/23i if the patient has concomitant IBD or if the patient prefers less frequent drug administration.	Low (89, 90, 92, 93, 98–100)
12. **Switch to an IL-17i biologic over switching to another OSM** (PICO 51) **Conditional recommendation** based on low-quality evidence; may consider switching to another OSM if the patient prefers an oral medication.	Low (83–86, 89, 90, 92, 93)
13. **Switch to an IL-12/23i biologic over switching to another OSM** (PICO 50) **Conditional recommendation** based on low-quality evidence; may consider switching to another OSM# if the patient prefers an oral medication over an injection, or if there are contraindications to an IL- 12/23i, such as severe recurrent infections.	Low (83–86, 98, 100)
In adult patients with active PsA and concomitant active IBD who are both OSM- and biologic treatment–naive,	
14. **Start a monoclonal antibody TNFi biologic over an OSM** (PICO 62) **Conditional recommendation** based on very-low-quality evidence; may consider starting an OSM if the patient prefers an oral medication, or if the patient has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.	Very low (114)
In adult patients with active PsA and concomitant active IBD despite treatment with an OSM,	
15. **Switch to a monoclonal antibody TNFi biologic over a TNFi biologic soluble receptor biologic (i.e., etanercept)** (PICO 58)	Moderate (115–117)
Strong recommendation supported by moderate-quality evidence, showing TNFi monoclonal antibody biologics are effective in IBD but indirect evidence shows a TNFi biologic soluble receptor biologic is not effective for the treatment of IBD.	
16. **Switch to a TNFi monoclonal antibody biologic over an IL-17i biologic** (PICO 59)	Moderate (50)
Strong recommendation supported by moderate-quality evidence showing monoclonal antibody TNFi biologics are effective for IBD while an IL-17i biologic is not effective for IBD.	
17. **Switch to a TNFi biologic monoclonal antibody biologic over an IL-12/23i biologic** (PICO 61) **Conditional recommendation** based on very-low-quality evidence; may consider switching to an IL- 12/23i biologic if the patient has contraindications to TNFi biologics, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease, or prefers less frequent drug administration.	Very low
18. **Switch to an IL-12/23i biologic over switching to an IL-17i biologic** (PICO 60)	Moderate (50)
Strong recommendation supported by moderate-quality evidence showing IL-12/23i biologic is effective for IBD while an IL-17i biologic is not effective for IBD.	

***** Active psoriatic arthritis (PsA) is defined as disease causing symptoms at an unacceptably bothersome level as reported by the patient, and judged by the examining clinician to be *due to PsA* based on ≥1 of the following: swollen joints, tender joints, dactylitis, enthesitis, axial disease, active skin and/or nail involvement, and extraarticular inflammatory manifestations such as uveitis or inflammatory bowel disease (IBD).
† When there were no published studies, we relied on the clinical experience of the panelists, which was designated very-low-quality evidence.
‡ Axial disease is generally treated according to the American College of Rheumatology/Spondylitis Association of America/Spondyloarthritis Research and Treatment Network recommendations for spondyloarthritis (SpA).
§ Because there are currently no widely agreed-upon definitions of disease severity, psoriasis severity should be established by the health care provider and patient on a case-by-case basis. In clinical trials, severe psoriasis has been defined as a Psoriasis Area and Severity Index (PASI) score (25) of ≥12 and a body surface area score of ≥10. In clinical practice, however, the PASI tool is not standardly utilized given its cumbersome nature. In 2007, the National Psoriasis Foundation published an expert consensus statement, which defined moderate-to-severe disease as a body surface area of ≥5% (68). In cases in which the involvement is in critical areas, such as the face, hands or feet, nails, intertriginous areas, scalp, or where the burden of the disease causes significant disability or impairment of physical or mental functioning, the disease can be severe despite the lower amount of surface area of skin involved. The need to factor in the unique circumstances of the individual patient is of critical importance, but this threshold provides some guidance in the care of patients.
¶ Oral small molecules (OSMs) are defined as methotrexate (MTX), sulfasalazine, leflunomide, cyclosporine, or apremilast and *do not* include tofacitinib, which was handled separately since its efficacy/safety profile is much different from that of other OSMs listed above. OSM- and biologic treatment–naive is defined as naive to treatment with OSMs, tumor necrosis factor inhibitors (TNFi,), interleukin-17 inhibitors (IL-17i), and IL-12/23i; patients may have received nonsteroidal antiinflammatory drugs (NSAIDs), glucocorticoids, and/or other pharmacologic and nonpharmacologic interventions.
# It should be noted that for the enthesitis questions (PICO 49, 50, and 51), the existing evidence was mainly drawn from the apremilast studies, as no randomized controlled trial report described enthesitis outcomes for the other OSMs.

Active PsA with predominant enthesitis in treatment-naive patients and despite treatment with an OSM (Table 5). *All recommendations for patients with active PsA with predominant enthesitis are conditional based on low- to very-low-quality evidence. (This section names apremilast among all OSMs specifically for recommendations, since of the OSMs, only apremilast has shown efficacy for enthesitis.)*

In treatment-naive PsA patients with predominant enthesitis, a TNFi biologic is recommended over an OSM as a first-line option. Apremilast may be used instead of a TNFi biologic if the patient prefers an oral therapy or has contraindications to TNFi. Oral NSAIDs are recommended over starting an OSM unless the patient has cardiovascular disease, peptic ulcer disease, renal disease (or impairment), or severe psoriasis or PsA, in which case apremilast may be given instead of NSAIDs. Tofacitinib is recommended over apremilast for treatment-naive patients with predominant enthesitis. Apremilast may be used instead of tofacitinib in patients with recurrent infections.

In patients with active PsA with predominant enthesitis despite treatment with an OSM (used for other manifestations of PsA), a TNFi biologic, an IL-17i biologic, or an IL-12/23i biologic is recommended over switching to another OSM. Apremilast may be used in patients who prefer oral therapy or who have recurrent infections or contraindications to TNFi biologics. A TNFi biologic is recommended over an IL-17i or IL-12/23i biologic. An IL-17i or IL-12/23i biologic may be used instead of a TNFi biologic in patients with severe psoriasis or contraindications to TNFi. An IL-17i biologic is recommended over an IL-12/23i biologic. An IL-12/23i biologic may be used instead of a TNFi biologic in patients who prefer less frequent drug administration, and instead of an IL-17i biologic in patients with concomitant IBD or who prefer less frequent drug administration.

Active PsA with concomitant active IBD (Table 5). *All recommendations for patients with active PsA with concomitant active IBD are strong based on moderate-quality evidence, except for 2 conditional recommendations based on very-low-quality evidence.*

Active PsA in OSM- and biologic treatment–naive patients with concomitant active IBD. In patients with active PsA with concomitant active IBD who have not received OSM or biologic treatment, a monoclonal antibody TNFi biologic (excludes etanercept, which is a fusion molecule/soluble receptor biologic) is recommended over an OSM (Table 5). An OSM may be used in patients without severe PsA who prefer oral therapy or have contraindications to TNFi biologics.

Active PsA despite treatment with an OSM in patients with concomitant active IBD. In patients with active PsA with concomitant active IBD despite treatment with an OSM, a monoclonal antibody TNFi biologic or an IL-12/23i biologic *should be used* over an IL-17i biologic, and a monoclonal antibody TNFi biologic *should be used* over a TNFi soluble receptor biologic (etanercept) (*all strong recommendations* [Table 5]). A monoclonal antibody TNFi biologic is recommended over an IL-12/23i biologic (conditional recommendation). An IL-12/23i biologic may be used instead of a monoclonal antibody TNFi biologic in patients with contraindications to TNFi biologics or who prefer less frequent drug administration.

Active PsA with comorbidities (Table 6). *All recommendations for patients with active PsA with comorbidities are conditional based on low- to very-low-quality evidence, except those for patients with serious infections, which are strong based on moderate-quality evidence.*

Active PsA in OSM- and biologic treatment–naive patients with concomitant diabetes. In patients with active PsA with concomitant active diabetes who have not received OSM or biologic treatment, an OSM other than MTX is recommended over a TNFi biologic, due to the concern about the higher prevalence of fatty liver disease and liver toxicity with MTX use in this patient population (39,40) (Table 6). A TNFi biologic may be used instead of an OSM in the presence of severe PsA or severe psoriasis or when diabetes is well controlled (i.e., with a potentially lower risk of infections).

Active PsA in OSM- and biologic treatment–naive patients with frequent serious infections. In patients with active PsA who have frequent serious infections and have not received OSM or biologic treatment, an OSM *should be used* over a TNFi biologic as a first-line treatment since there is a black box warning against the use of a TNFi biologic in patients with frequent serious infections (*strong recommendation*). An IL-12/23i or IL-17i biologic is recommended over a TNFi biologic (conditional recommendation [Table 6]). A TNFi biologic may be used instead of an IL-12/23i biologic in patients with severe PsA and instead of an IL-17i biologic in patients with concomitant IBD.

Active PsA in patients requiring killed or live attenuated vaccinations when starting biologic treatment (Table 7). *All recommendations for vaccinations in patients with active PsA are conditional based on very-low-quality evidence.*

It is recommended that the biologic treatment be started and the killed vaccines administered (as indicated based on patient age, sex, and immunization history per recommendations of the Centers for Disease Control and Prevention [41]) in patients with active PsA over delaying the biologic to give the killed vaccines. Delaying the start of the biologic is recommended over not delaying to administer a live attenuated vaccination in patients with active PsA (Table 7). If PsA manifestations are severe and delaying the start of the biologic is not desirable, starting the biologic and administering the live attenuated vaccines at the same time might be considered.

Table 6. Recommendations for treatment of patients with active psoriatic arthritis and comorbidities, including concomitant diabetes and recurrent serious infections (PICOs 63–66)*

	Level of evidence (evidence [refs.] reviewed)†
In adult patients with active PsA and diabetes who are both OSM- and biologic treatment–naive,‡	
1. **Start an OSM other than MTX over a TNFi biologic** (PICO 63a) **Conditional recommendation** based on very-low-quality evidence; may consider starting a TNFi, if the patient has severe PsA§ or severe/active skin disease,¶ when diabetes is well controlled.	Very low (118, 119)
In adult patients with active PsA and frequent serious infections who are both OSM- and biologic treatment–naive,	
2. **Start an OSM over a TNFi biologic** (PICO 64) **Strong recommendation** supported by moderate-quality evidence, including a black box warning against the use of a TNFi biologic with regard to increased risk of serious infection.	Moderate (33, 120)
3. **Start an IL-12/23i biologic over a TNFi biologic** (PICO 65) **Conditional recommendation** based on very-low-quality evidence; may consider starting a TNFi if the patient has severe PsA.	Very low (33)
4. **Start an IL-17i biologic over a TNFi biologic** (PICO 66) **Conditional recommendation** based on very-low-quality evidence; may consider starting a TNFi biologic in patients with concomitant IBD.	Very low

* Active psoriatic arthritis (PsA) is defined as disease causing symptoms at an unacceptably bothersome level as reported by the patient, and judged by the examining clinician to be *due to PsA* based on ≥1 of the following: swollen joints, tender joints, dactylitis, enthesitis, axial disease, active skin and/or nail involvement, and extraarticular inflammatory manifestations such as uveitis or inflammatory bowel disease (IBD).
† When there were no published studies, we relied on the clinical experience of the panelists, which was designated very-low-quality evidence.
‡ Oral small molecules (OSMs) are defined as methotrexate (MTX), sulfasalazine, leflunomide, cyclosporine, or apremilast and *do not* include tofacitinib, which was handled separately since its efficacy/safety profile is much different from that of other OSMs listed above. OSM- and other treatment–naive is defined as naive to treatment with OSMs, tumor necrosis factor inhibitors (TNFi), interleukin-17 inhibitors (IL-17i), and IL-12/23i; patients may have received nonsteroidal antiinflammatory drugs, glucocorticoids, and/or other pharmacologic and nonpharmacologic interventions.
§ Because there are currently no widely agreed-upon definitions of disease severity, PsA severity should be established by the health care provider and patient on a case-by-case basis. For the purposes of these recommendations, severity is considered a broader concept than disease activity in that it encompasses the level of disease activity at a given time point, as well as the presence of poor prognostic factors and long-term damage. Examples of severe PsA disease include the presence of ≥1 of the following: a poor prognostic factor (erosive disease, elevated levels of inflammation markers such as C-reactive protein or erythrocyte sedimentation rate attributable to PsA), long-term damage that interferes with function (e.g., joint deformities, vision loss), highly active disease that causes major impairment in quality of life (i.e., active psoriatic inflammatory disease at many sites [including dactylitis, enthesitis] or function-limiting inflammatory disease at few sites), and rapidly progressive disease.
¶ Because there are currently no widely agreed-upon definitions of disease severity, psoriasis severity should be established by the health care provider and patient on a case-by-case basis. In clinical trials, severe psoriasis has been defined as a Psoriasis Area and Severity Index (PASI) score (25) of ≥12 and a body surface area score of ≥10. In clinical practice, however, the PASI tool is not standardly utilized given its cumbersome nature. In 2007, the National Psoriasis Foundation published an expert consensus statement, which defined moderate-to-severe disease as a body surface area of ≥5% (68). In cases in which the involvement is in critical areas, such as the face, hands or feet, nails, intertriginous areas, scalp, or where the burden of the disease causes significant disability or impairment of physical or mental functioning, the disease can be severe despite the lower amount of surface area of skin involved. The need to factor in the unique circumstances of the individual patient is of critical importance, but this threshold provides some guidance in the care of patients.

Recommendations for nonpharmacologic interventions in patients with active PsA regardless of pharmacologic treatment status (Table 8)

All recommendations for nonpharmacologic interventions for patients with active PsA are conditional based on low- to very-low-quality evidence, except that for smoking cessation, which is a strong recommendation.

It is recommended that patients with active PsA use some form or combination of exercise, physical therapy, occupational therapy, massage therapy, and acupuncture over not using these modalities as tolerated. Low-impact exercise (e.g., tai chi, yoga, swimming) is recommended over high-impact exercise (e.g., running). High-impact exercises may be performed instead of low-impact exercises by patients who prefer the former and

Table 7. Recommendations for vaccination in patients with active psoriatic arthritis (PICOs 56–57)*

	Level of evidence (evidence [refs.] reviewed)†
In adult patients with active PsA needing vaccinations,‡	
1. **Start the biologic and administer killed vaccines over delaying the start of biologic to administer killed vaccines** (PICO 56) **Conditional recommendation** based on very-low-quality evidence; may consider delaying the start of biologic to administer killed vaccines due to patient preference based on patient belief about vaccine efficacy.	Very low (121–126)
2. **Delay the start of biologic to administer live attenuated vaccines over starting the biologic and administering live attenuated vaccines** (PICO 57) **Conditional recommendation** based on very-low-quality evidence; may consider starting the biologic and administering live attenuated vaccines in patients with very active severe joint§ or skin¶ disease who prefer no delay in biologic initiation.	Very low (127)

* Active psoriatic arthritis (PsA) is defined as disease causing symptoms at an unacceptably bothersome level as reported by the patient, and judged by the examining clinician to be *due to PsA* based on ≥1 of the following: swollen joints, tender joints, dactylitis, enthesitis, axial disease, active skin and/or nail involvement, and extraarticular inflammatory manifestations such as uveitis or inflammatory bowel disease.
† When there were no published studies, we relied on the clinical experience of the panelists, which was designated very-low-quality evidence.
‡ Vaccines as indicated by patient age, sex, and immunization history per recommendations from the Centers for Disease Control and Prevention and available at: https://www.cdc.gov/vaccines/schedules/downloads/adult/adult-combined-schedule.pdf.
§ Because there are currently no widely agreed-upon definitions of disease severity, PsA severity should be established by the health care provider and patient on a case-by-case basis. For the purposes of these recommendations, severity is considered a broader concept than disease activity in that it encompasses the level of disease activity at a given time point, as well as the presence of poor prognostic factors and long-term damage. Examples of severe PsA disease include the presence of ≥1 of the following: a poor prognostic factor (erosive disease, elevated levels of inflammation markers such as C-reactive protein or erythrocyte sedimentation rate attributable to PsA), long-term damage that interferes with function (e.g., joint deformities, vision loss), highly active disease that causes major impairment in quality of life (i.e., active psoriatic inflammatory disease at many sites [including dactylitis, enthesitis] or function-limiting inflammatory disease at few sites), and rapidly progressive disease.
¶ Because there are currently no widely agreed-upon definitions of disease severity, psoriasis severity should be established by the health care provider and patient on a case-by-case basis. In clinical trials, severe psoriasis has been defined as a Psoriasis Area and Severity Index (PASI) score (25) of ≥12 and a body surface area score of ≥10. In clinical practice, however, the PASI tool is not standardly utilized given its cumbersome nature. In 2007, the National Psoriasis Foundation published an expert consensus statement, which defined moderate-to-severe disease as a body surface area of ≥5% (68). In cases in which the involvement is in critical areas, such as the face, hands or feet, nails, intertriginous areas, scalp, or where the burden of the disease causes significant disability or impairment of physical or mental functioning, the disease can be severe despite the lower amount of surface area of skin involved. The need to factor in the unique circumstances of the individual patient is of critical importance, but this threshold provides some guidance in the care of patients.

have no contraindications to high-impact exercises (Table 8). Clinicians *should* encourage patients to stop smoking, offering cessation aids, due to a demonstrated effectiveness of smoking cessation in randomized trials in other conditions and in the general population (42–44) (*strong recommendation*). In PsA patients who are overweight or obese, weight loss is recommended in order to potentially increase pharmacologic response.

All strong recommendations in this guideline are also listed separately in Supplementary Appendix 6, at http://onlinelibrary.wiley.com/doi/10.1002/art.40726/abstract.

DISCUSSION

We present herein the first ACR/NPF guideline for the treatment of psoriatic arthritis. The goal of this guideline is to assist health care providers in managing active PsA in their patients, including optimizing therapy. PsA is a heterogeneous and multifaceted inflammatory disease, and its different clinical features (e.g., peripheral arthritis, psoriasis, nail disease, enthesitis, dactylitis, axial disease) sometimes respond differently to therapy. Despite an expansion in the number of new therapies for PsA, there remains limited comparative efficacy/effectiveness evidence to inform treatment decisions. Thus, most of our recommendations are based on low-quality evidence and are conditional. The conditional recommendations convey that, although the suggested course of action will be best for many patients, there will be some patients in whom, considering their comorbidities and/or their values and preferences, the alternative represents the best choice. The guideline will be updated as new evidence from comparative studies becomes available.

A Patient Panel meeting was held prior to the Voting Panel meeting to gain insight into patients' values and preferences for the pharmacologic/nonpharmacologic intervention comparisons being addressed. We recognize that patient preferences are an important part of our treatment recommendations. Findings from the Patient Panel meeting were discussed throughout the Voting Panel

Table 8. Recommendations for treatment of patients with active psoriatic arthritis with nonpharmacologic interventions (PICOs 1–8)*

	Level of evidence (evidence [refs.] reviewed)†
In adult patients with active PsA,	
1. **Recommend exercise over no exercise** (PICO 1) **Conditional recommendation** based on low-quality evidence; may consider no exercise in patients with existing muscle/tendon injury or multiple inflamed symptomatic joints with worsening pain with exercise.	Low (128)
2. **Recommend low-impact exercise (e.g., tai chi, yoga, swimming) over high-impact exercise (e.g., running)** (PICO 2) **Conditional recommendation** based on very-low-quality evidence; may consider high-impact exercise due to patient preference.	Very low
3. **Recommend physical therapy over no physical therapy** (PICO 3) **Conditional recommendation** based on very-low-quality evidence; may consider no physical therapy due to patient preference, out-of-pocket cost, distance to physical therapy site, or lack of transportation.	Very low
4. **Recommend occupational therapy over no occupational therapy** (PICO 4) **Conditional recommendation** based on low-quality evidence; may consider no occupational therapy due to patient preference, out-of-pocket cost, distance to occupational therapy site, or lack of transportation.	Low (129, 130)
5. **Recommend weight loss over no weight loss for patients who are overweight/obese** (PICO 5) **Conditional recommendation** based on low-quality evidence; may consider no weight loss due to additional patient burden involved with weight-loss program.	Low (131–133)
6. **Recommend massage therapy over no massage therapy** (PICO 7) **Conditional recommendation** based on very-low-quality evidence; may consider no massage therapy due to associated costs.	Very low (134)
7. **Recommend acupuncture over no acupuncture** (PICO 8) **Conditional recommendation** based on very-low-quality evidence; may consider no acupuncture due to associated costs.	Very low (135)
8. **Recommend smoking cessation over no smoking cessation** (PICO 6) **Strong recommendation** supported by moderate-quality evidence, rated down for indirectness.	Moderate (136, 137)

* Active psoriatic arthritis (PsA) is defined as disease causing symptoms at an unacceptably bothersome level as reported by the patient, and judged by the examining clinician to be *due to PsA* based on ≥1 of the following: swollen joints, tender joints, dactylitis, enthesitis, axial disease, active skin and/or nail involvement, and extraarticular inflammatory manifestations such as uveitis or inflammatory bowel disease.
† When there were no published studies, we relied on the clinical experience of the panelists, which was designated very-low-quality evidence.

meeting to ensure that patient input was incorporated into the final PsA guideline. Examples of patient feedback included strong value on therapies that are effective (e.g., prevent further damage, and improve quality of life, social participation, and function) and safe (especially having low adverse event profiles). In particular, patients discussed the negative impact of adverse events (e.g., fatigue, nausea, and malaise) on quality of life and social participation, and thus the risk for these adverse events weighed heavily in patients' decision-making. The concept of treat-to-target was challenging for patients. Although they saw value in improved outcomes, they also thought this strategy could increase costs to the patient (e.g., copayments, time traveling to more frequent appointments, etc.) and potentially increase adverse events. Therefore, a detailed conversation with the patient is needed to make decisions regarding treat-to-target. To help ensure that the recommendations were patient-centered, 2 patients were members of the Voting Panel.

While using a treat-to-target approach over not using a treat-to-target approach was discussed by the Voting Panel, we did not address specific targets to be recommended or used. There have been 2 international meetings to discuss potential targets: the use of either minimal disease activity (MDA) or disease activity in psoriatic arthritis (DAPSA) (45,46). The treatment target for PsA would likely be MDA or DAPSA, although a different target may be chosen through patient–provider discussion.

The ACR/NPF PsA guideline conditionally recommends a TNFi biologic over an OSM agent in patients with active PsA. The

available low-quality evidence is inconclusive regarding the efficacy of OSMs in management of PsA, whereas there is moderate-quality evidence of the benefits of TNFi biologics, in particular regarding their impact on the prevention of disease progression and joint damage. In making their recommendation, the panel recognized the cost implications, but put considerations of quality of evidence for benefit over other considerations. This guideline provides recommendations for early and aggressive therapy in patients with newly diagnosed PsA.

The recommendation is, however, conditional, and the panel recognized several potential exceptions to it. Circumstances in which a patient may choose an OSM over a TNFi biologic may include mild-to-moderate disease, a preference of oral over parenteral therapy, or concerns regarding adverse effects of a biologic. A TNFi biologic would not be a good choice in patients with contraindications, including congestive heart failure, previous serious infections, recurrent infections, or demyelinating disease.

During the development of the Group for Research and Assessment of Psoriasis and Psoriatic Arthritis recommendations (47) and the European League Against Rheumatism (EULAR) recommendations (48) for the treatment of PsA, panel members also challenged the decision to put OSMs first in those recommendations. For the EULAR recommendations, the final decision was made based on the lower cost of these medications, a consideration our panel placed lower than the quality of evidence for benefit.

In patients with concomitant IBD, the Voting Panel made strong recommendations favoring a monoclonal antibody TNFi or an IL-12/23i biologic over an IL-17i biologic or a TNFi receptor biologic (etanercept). This was based on moderate-quality evidence showing that TNFi biologics and ustekinumab (an IL-12/23i biologic) are effective for the management of IBD, whereas etanercept (a TNFi receptor biologic) and secukinumab (an IL-17i biologic) are not (49,50).

When the evidence was low or very-low quality, the panel could not be confident in the judgment of net benefit—thus the conditional recommendation. Often, low- or very-low-quality evidence came from indirect evidence, for instance from rheumatoid arthritis (33) or, in the absence of studies, from clinical experience (Supplementary Appendix 5, on the Arthritis & Rheumatology web site at http://onlinelibrary.wiley.com/doi/10.1002/art.40726/abstract). When data on comparative benefits and comparative harms were similar between two medications, the panel explicitly preferred and recommended the medication for which longer-term harms were more well-known, and in which the physician experience in patients with PsA was longer, supplementing with harms data/experience from related rheumatic conditions, where these medications are commonly used. In each case, judgments of net benefit involved explicit consideration of values and preferences, including input from Patient Panel members of the Voting Panel as well as the full Patient Panel that met prior to the Voting Panel meeting.

We recognize that these recommendations do not account for the full complexity of PsA or the full range of possible therapies (e.g., glucocorticoids were not addressed). The high degree of heterogeneity in the presentation and course of PsA coupled with the involvement of multiple domains in a single patient cannot be captured in a single algorithm. In addition, reporting of disease measures and differences in inclusion/exclusion criteria in PsA clinical trials makes it difficult to compare therapies across trials. The impact of alternative therapies on important outcomes such as joint damage still remains to be elucidated. Vaccination recommendations with tofacitinib were not included, as it was not yet approved for PsA when the PICO questions were drafted and only a limited number of PICO questions could be feasibly included for voting. Additional topics, including vaccination in the setting of tofacitinib, will be addressed in a subsequent guideline update.

The ACR has decided to use GRADE methodology in the development of guidelines for the management of rheumatic diseases. The GRADE methodology specifies that panels make recommendations based on a consideration of the balance of relative benefits and harms of the treatment options under consideration, the quality of the evidence (i.e., confidence in the evidence based on the lowest quality of the critical outcomes—high, moderate, low, or very low), and patients' values and preferences. The rating of the quality of evidence for each clinical situation (PICO question) helped to inform the strength of the recommendation (strong or conditional) (51).

The use of GRADE (not used in other PsA treatment recommendations) allowed an explicit consideration of the overall evidence, including the balance of benefits and harms of treatments, the incorporation of patient values and preferences, and cost considerations to judge the tradeoff. This approach led to transparency in decision making by the Voting Panel for each clinical scenario and the formulation of these recommendations. Consistent with GRADE guidance, the Voting Panel usually offered a strong recommendation in the presence of moderate- or high-quality rating of the evidence, and a conditional recommendation in the presence of very-low or low-quality evidence (although recommendations can also be conditional in the setting of moderate-quality evidence, and in certain circumstances strong in the face of low-quality evidence) (15). The other merits of the ACR/NPF process undertaken included a comprehensive literature search, the consideration of each comparison in light of the available evidence, the diverse composition of the Voting Panel, the inclusion of all of the available therapies (e.g., IL-17i biologics, an IL-12/23i biologic, abatacept, and tofacitinib) in the decision-making process (including those approved for psoriasis or rheumatoid arthritis but not yet for PsA, ensuring that the guideline would not be out of date by the time it was published), and the inclusion of population subsets, such as those with predominant enthesitis and/or IBD.

Limitations of the guideline include the limited comparative evidence to inform selection of therapies (i.e., primary comparative benefit/efficacy and harms evidence) and the inability to include all possible clinical scenarios due to the necessity of keeping the task feasible. Because the American Academy of Dermatology and the NPF are currently developing a guideline addressing therapy for psoriasis, our guideline did not address treatment of isolated psoriasis. Another limitation is that we searched only English-language literature. The major limitation of the work arises from the limitations in the evidence.

In this guideline, we often used indirect comparisons among trials/therapies, frequently relying on network meta-analysis. Stratified analyses among subgroups (e.g., treatment-naive, inadequate response to a TNFi biologic agent) were rarely reported separately in primary trials, limiting our ability to perform network meta-analyses in these important subgroups. For most clinical scenarios (PICO questions) there were few or no head-to-head comparison studies identified in the literature review. Thus, the quality of evidence was most often low or very low, and only occasionally moderate (Supplementary Appendix 5; http://onlinelibrary.wiley.com/doi/10.1002/art.40726/abstract). This led to nearly all recommendations being conditional, with a few strong recommendations in cases in which there was sufficient evidence (including that from outside of PsA) to make the Voting Panel confident in selecting one option over the comparator. A flow chart or ranking of treatments requires strong recommendation; when recommendations are conditional/weak it means that the right course of action differs between patients. When the right course of action differs between patients, it is inappropriate to make the flow chart and establish treatment ranking or a hierarchy of treatment options (14).

The 2018 ACR/NPF guideline for the treatment of PsA will assist patients and their health care providers in making challenging disease management decisions. More comparative data are needed to inform treatment selection. Several ongoing trials, including a trial to compare a TNFi biologic combination therapy with a TNFi biologic monotherapy and MTX monotherapy (52), will inform treatment decisions. We anticipate future updates to the guideline when new evidence is available.

ACKNOWLEDGMENTS

We thank Ms Emily Boyd with the NPF for her involvement throughout the guideline development process. We thank Dr. Maureen Dubreuil for leading the Patient Panel meeting, as well the patients who participated in this guideline project: Eddie Applegate, Steve Bishkoff, Christy Gephart, Lisa Medlin, Gail C. Richardson, Richard F. Seiden, Delores Teddleton, and Hilary Wilson. We thank the ACR staff, including Ms Regina Parker for assistance in organizing the face-to-face meeting and coordinating the administrative aspects of the project and Ms Robin Lane for assistance in manuscript preparation. We thank Ms Janet Joyce for help in developing the literature search strategy and performing the literature search and updates, and Ms Tamara Rader for peer-reviewing the literature search strategy. We thank Dr. Jonathan Treadwell for his statistical contributions to the network meta-analyses that were done as part of the literature review.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Dr. Singh had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

The 2022 British Society for Rheumatology guideline for the treatment of psoriatic arthritis with biologic and targeted synthetic DMARDs

Laura Tucker[1,2], Alexander Allen[3], David Chandler[4], Coziana Ciurtin [5], Andrew Dick[6,7], Amy Foulkes [8,9], Nicola Gullick[10], Philip Helliwell[11], Deepak Jadon [12,13], Gareth Jones [14], Stuart Kyle[15], Vishnu Madhok[16], Neil McHugh [17], Andrew Parkinson[18], Tim Raine[19], Stefan Siebert [20], Catherine Smith [21], William Tillett [22,*] and Laura C. Coates [2,*]

Key words: PsA, biologics, targeted synthetic DMARDs, treatment, management, guideline, recommendations, psoriasis, enthesitis, dactylitis

Background

PsA is a chronic, inflammatory, musculoskeletal disease affecting approximately one quarter of people with the skin condition psoriasis [1, 2]. PsA is a highly heterogeneous disease, encompassing diverse musculoskeletal manifestations or 'domains' resulting from disease activity in different tissues. These include peripheral arthritis, spondylitis (axial inflammation), dactylitis (inflammation of the whole digit) and enthesitis (inflammation where a tendon, ligament or joint capsule insert to the bone). Unlike RA, there is a significant variability in clinical presentation of PsA. Individuals with PsA may have different domains involved and drugs have different levels of effectiveness on each domain. It is therefore essential that clinical guidelines for the treatment selection in PsA include disease phenotype and differential effect of medication.

PsA is a potentially debilitating and destructive disease, with half of people developing irreversible joint damage within 2 years [3]. This results in significant functional limitations, depression and anxiety, as well as negatively impacting on education, work capacity and social participation [4–8]. Furthermore, PsA is associated with extra-articular manifestations, including inflammatory bowel disease (Crohn's disease and ulcerative colitis) and uveitis. In addition, metabolic syndrome (obesity, diabetes, hypertension, hyperlipidaemia, fatty liver disease) and cardiovascular disease are more

NICE has accredited the process used by BSR to create its clinical guidelines. The term began on 27 February 2012 and the current renewed accreditation is valid until 28 January 2023. More information on accreditation can be viewed at www.nice.org.uk/accreditation.

common compared with the prevalence in the general population [7, 9, 10]. All of these factors may influence treatment selection [11] and potentially modifiable risk factors, such as obesity and smoking, which can impact therapeutic response and prognosis, should be addressed within the management plan.

There is strong evidence that a treat-to-target (T2T) approach to PsA management, aiming for remission or low disease activity, results in better clinical, radiographic and patient-reported outcomes [12, 13]. Significant advances in therapeutic options available for PsA now mean a target of remission is an achievable goal. Despite PsA being a highly heterogeneous disease, most physicians apply the same step-up therapy to all people with peripheral arthritis, owing to the lack of comparative evidence. Initially a single conventional systemic disease-modifying anti-rheumatic drug (csDMARD) is used, with methotrexate typically being prescribed first-line. This is followed by use of an alternative single csDMARD or combinations of csDMARDs, prior to biologic use if the previous treatment step is unsuccessful [11, 14]. Up to 50% of people with PsA require biologic or targeted synthetic (b/ts)DMARD therapy [15] and treatment in the UK is governed by specific agencies, owing to the higher cost of these drugs. This includes recommendations in England from the National Institute for Health and Care Excellence (NICE) criteria and in Scotland from the Scottish Medicines Consortium (SMC). In addition, non-steroidal anti-inflammatory drugs and local corticosteroids are frequently used, which although not optimal for long-term use, do offer quick, short-term symptomatic relief, while DMARDs take effect.

In practice, biologics require use for a minimum of 12 (e.g. TNFi) or 16 weeks (e.g. IL-17Ai), before response can be evaluated [16]. Unfortunately, a proportion of people do not respond to the first-line drug chosen (primary non-response), while other people respond well initially, but subsequently lose response (secondary non-response). For these reasons, as well as adverse events encountered by some people, switching therapy is required to achieve and maintain treatment targets.

Need for updating of guideline

The last British Society for Rheumatology (BSR) guideline for the treatment of PsA was published in 2012 [12] and focussed specifically on TNF inhibitors as they were the only biologic DMARDs (bDMARDs) available. Since that time, there have been significant advances in therapeutic options available for PsA and drugs with different modes of action are now available, including IL17, IL12/23, IL23 p19, Cytotoxic T-lymphocyte-Associated antigen 4 (CTLA4-Ig), Phosphodiesterase-4 (PDE4) and Janus kinase (JAK) inhibition (i).

We recognize existing high-quality international treatment recommendations, which include those written by the Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) in 2021, EULAR in 2020 and American College of Rheumatology in 2018 [13, 17, 18]. However, these are generic to many international health settings and do not provide specific guidance for the UK, taking account of the healthcare system and prescribing restrictions. This guideline aims to look at the evidence beyond current NICE technology appraisals and to provide advice for the management of people with PsA.

Objectives

This guideline offers systematic and evidence-based recommendations to support UK clinicians in the prescription of bDMARD and tsDMARD therapies in adults with PsA. The guideline also includes guidance for managing those patients with extra-articular manifestations [uveitis and inflammatory bowel disease (IBD)], as well as those who smoke or are overweight. The guideline provides a stepwise management plan giving clear advice on treatment, including drug eligibility, sequencing, switching and treatment strategy.

This guideline complements existing BSR guidelines and therefore does not include:

i. detailed assessment of the safety of bDMARDs;
ii. biologic or tsDMARD therapies for juvenile idiopathic arthritis;
iii. use of csDMARDs in PsA;
iv. use of biologics or tsDMARDs in pregnancy; or
v. biologic or tsDMARD therapies for adults with psoriatic disease confined to the skin only (in this situation, please refer to BAD guidelines for management of psoriasis at https://www.bad.org.uk/healthcare-professionals/psoriasis).

Target audience

The guideline has been developed to provide assistance to rheumatologists, dermatologists and other clinicians involved in the prescription of biologics and tsDMARDs for people with PsA. The guideline will also assist specialist nurses and allied health professionals (AHPs) in the assessment of treatment response, drug sequencing and switching and provide information to people with PsA who are receiving or moving towards biologic or tsDMARD therapy.

Stakeholder involvement

The guideline has been developed by a multidisciplinary guideline working group (GWG) set up by BSR, including rheumatologists, dermatologists, an ophthalmologist, a gastroenterologist, a general practitioner, an epidemiologist, a specialist nurse and patient representatives. Any conflicts of interest among the GWG were fully declared. Details of members of this working party and their declared conflicts of interest are included at the end of this article and are available on the BSR website. The guideline was presented for comment at the BSR Annual Meeting in 2022 and was available for open consultation on the BSR website for a month prior to submission for publication. Opinions of key stakeholders, including members of the BSR, and Primary

Downloaded from https://academic.oup.com/rheumatology/article/61/9/e255/6594139 by guest on 03 February 2023

Care Rheumatology and Musculoskeletal Medicine Society (PCRMM), as well as patient members of the Psoriasis and Psoriatic Arthritis Alliance (PAPAA), were also sought.

Rigour of development

This guideline and recommendations were developed in line with BSR's Guidelines Protocol [19], which has National Institute for Health and Care Excellence (NICE) accreditation. The guideline and recommendations were underpinned with a systematic literature review.

Literature review

The evidence used to develop this guideline was compiled from a systematic literature review (SLR), including electronic bibliographic databases (Medline and Embase) and the Cochrane Database of Systematic Reviews up to 10 December 2020. Key terms for the search were the following: MeSH terms arthritis, psoriatic, psoriatic arthritis, psoriasis and arthritis in combination (independently) with biologic therapy mode of action, targeted synthetic mode of action or any biologic or tsDMARD drug name. Inclusion criteria for review were clinical outcomes in adults with PsA, published in English or in languages other than English with an English translation available. All titles and abstracts were screened by the BSR systematic literature reviewer and full papers of relevant material were obtained. In addition, data extraction and quality assessment undertaken by the Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) [20] was utilized to aid in the completion of this SLR. Reviews of the articles included were conducted to establish current evidence for the following topics: efficacy of TNF inhibitors, IL-12/23 inhibitors, IL-23 inhibitors, IL-17 inhibitors, abatacept, apremilast or JAK inhibitors in different disease domains (peripheral arthritis, axial disease, enthesitis, dactylitis) as well as extra-articular diseases (psoriasis, uveitis and inflammatory bowel disease), the clinical effectiveness of a treat-to-target strategy, the impact of bDMARD or tsDMARD tapering and dose reduction in remission, switching to a biosimilar drug, use of concomitant csDMARDs, efficacy of biologic and tsDMARD therapies in people who are overweight or smoke and the clinical effects of weight loss and smoking cessation in adults with active PsA. These key questions were agreed by the GWG prior to the literature search and published in the guideline scope [21].

In relation to efficacy, only randomized controlled trials (RCTs) of high quality were included for musculoskeletal and skin features of psoriatic disease, whereas in other areas, given the paucity of published data, wider data were included. Data from relevant articles were extracted using standardized literature evaluation forms in order to summarize evidence. Evidence for all aspects of the guideline was limited to articles published in peer-reviewed medical journals. There is a wealth of evidence concerning efficacy and safety of the bDMARDs and tsDMARDs available in PsA but a limited amount of evidence available to support recommendations on choice of therapy and treatment strategy.

Level of evidence

This guideline was developed in line with BSR's Guidelines Protocol [19]. The GWG convened on five occasions to review evidence and formulate recommendations. A draft document of the guideline was circulated to the full GWG for review. Each suggested recommendation in the final document was evaluated by all members and subjected to a vote relating to strength of agreement on a scale of 1 (total disagreement) to 10 (total agreement). The strength of agreement across the GWG for each recommendation is presented as the mean of the members' individual strength of recommendation, expressed as a percentage (e.g. 100% implies all responses were 10/10). The recommendation statements are presented at the beginning of each section. The GRADE approach to assessing the quality and strength of recommendations was adopted [22]. In addition, and in accordance with the BSR protocol accompanying each recommendation in parenthesis is a statement reflecting the strength of recommendation and quality of supporting evidence.

Strength of the recommendation

A strong recommendation to offer (or not to offer) something, where the benefits clearly outweigh the risks (or vice versa) for nearly all patients, is denoted by the number 1 in the guideline. A conditional recommendation (to consider or not) is made either when the risks and benefits are more closely balanced or are more uncertain and is denoted by the number 2 in this guideline.

Quality of evidence

Assessment of supporting evidence quality in GRADE reflects confidence in the estimates of benefits, harms and burdens. This guideline uses three levels and a letter (A, B, C) to reflect high, moderate or low/very low quality of evidence.

High quality is where further research is very unlikely to change the confidence in the estimate of effect.

Moderate quality is where further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate.

Low quality is where further research is very likely to have an important impact on confidence in the estimate of effect and is likely to change the estimate.

Very low-quality is where any estimate of effect is very uncertain.

Plan for review

The planned review date for this guideline will be in five years' time. However, important interim changes will be updated on the BSR website.

The guideline

Each of the seven sections of the guideline (overarching recommendations, treatment by disease domain, psoriasis and uveitis, IBD, treatment strategy, prescribing/switching, lifestyle choices) will now be discussed in detail. For each statement, a review of the evidence will follow.

New treatment algorithm

The guideline includes a new and expanded treatment algorithm incorporating all the modes of action available. The algorithm is intended to be practical and accessible 'at a glance' to practicing clinicians. The algorithm is underpinned by the key principle of thorough disease assessment to adequately understand disease phenotype and therefore to facilitate selection of b/tsDMARDs based on the domains of disease. The step-up algorithm incorporates the treat-to-target approach, the importance of considering comorbidities and associated conditions. See Fig. 1 for the new treatment algorithm.

Overarching generic recommendations and levels of agreement

GRADE recommends that where it is generally agreed by the medical community that certain principles of diagnosis and disease will do more good than harm (or vice versa), then these should be stated in terms of 'good practice statements' or generic recommendations [23]. The generic recommendations within this guideline are not necessarily evidence-based; however, they are a description of generally accepted best medical practice agreed within our GWG.

i. Therapeutic decisions need to be individualized and should be based on shared decision making between people with psoriatic arthritis and their clinicians [strength of agreement (SoA) 98%].
ii. All medication decisions in people with PsA should take into account: disease presentation with activity in the different domains below, previous medication use, associated conditions such as psoriasis, uveitis and IBD, other comorbidities and patient preference (SoA 97%).
iii. When a range of clinically suitable and equivalent treatments are being considered by people with psoriatic arthritis and their clinicians, select the least expensive, taking into account administration costs, dosage, price per dose and commercial arrangements (SoA 88%).
iv. If people with PsA have an inadequate response to a b/tsDMARD, consider potential factors that could be addressed including: confirming correct diagnosis, adherence, pain due to other causes, drug levels and immunogenicity (SoA 95%).

While discussions about treatments may be discussed with wider members of the rheumatology team, we suggest that commencing a bDMARD or tsDMARD for PsA remains a decision that should be made by a rheumatology consultant.

Treatment by domains

Peripheral arthritis (mono-, oligo- and polyarthritis)

i. In people with active psoriatic arthritis (defined as at least three tender and three swollen joints or those with fewer joints and either poor prognostic markers or severe disease impact defined as $\geq$2 domains involved, extraarticular involvement or impaired quality of life), with inadequate response or intolerance to one csDMARD, consider escalation to b/tsDMARDs (GRADE 2A, SoA 98%).

This recommendation refers to people with active peripheral PsA (at least three tender and three swollen joints or those with fewer joints but severe disease impact), with an inadequate response or intolerance to a csDMARD (methotrexate, leflunomide, sulfasalazine). In these individuals, escalation to a b/tsDMARD should be considered. This eligibility recommendation was made through group consensus and would bring the UK in line with the majority of European healthcare settings. However, the use of biologics after one csDMARD or for people with less than three tender/swollen joints is not currently permitted by NICE TAGs. A full assessment of evidence for csDMARD effectiveness was beyond the scope of this guideline, which focusses on biologic and tsDMARD treatments. The GWG discussed the appropriateness of initiating a b/tsDMARD first-line, taking into consideration the efficacy, safety and cost effectiveness of conventional synthetic, biologic and tsDMARDS. Based on anecdotal and observational data supporting the efficacy of csDMARDs, especially methotrexate, in achieving low disease activity/remission in PsA and from a cost-effective perspective, the group agreed that a csDMARD should be initiated first-line. There is little evidence to base a judgement on how many csDMARDs should be failed before considering a b/tsDMARD therapy; however, two relevant randomized controlled trials addressing eligibility for b/tsDMARDs were discussed: the SEAM-PsA and the CONTROL studies. The SEAM-PsA trial compared etanercept to etanercept plus methotrexate combination therapy and methotrexate monotherapy. The results demonstrated superiority of etanercept over methotrexate [24]. The CONTROL trial compared dose escalation of methotrexate to the addition of TNFi in people with inadequate disease control PsA after initial methotrexate therapy. A significantly higher proportion of individuals achieved minimal disease activity (MDA) at week 16 after introducing adalimumab compared with dose escalation of methotrexate [25]. The GWG therefore proposed earlier use of a b/tsDMARD therapy after failure of just one csDMARD be considered in those individuals with poor prognostic factors (polyarticular disease, high systemic inflammation levels, presence of radiographic erosions or significantly impaired functional ability) [6, 26–29] or severe active disease.

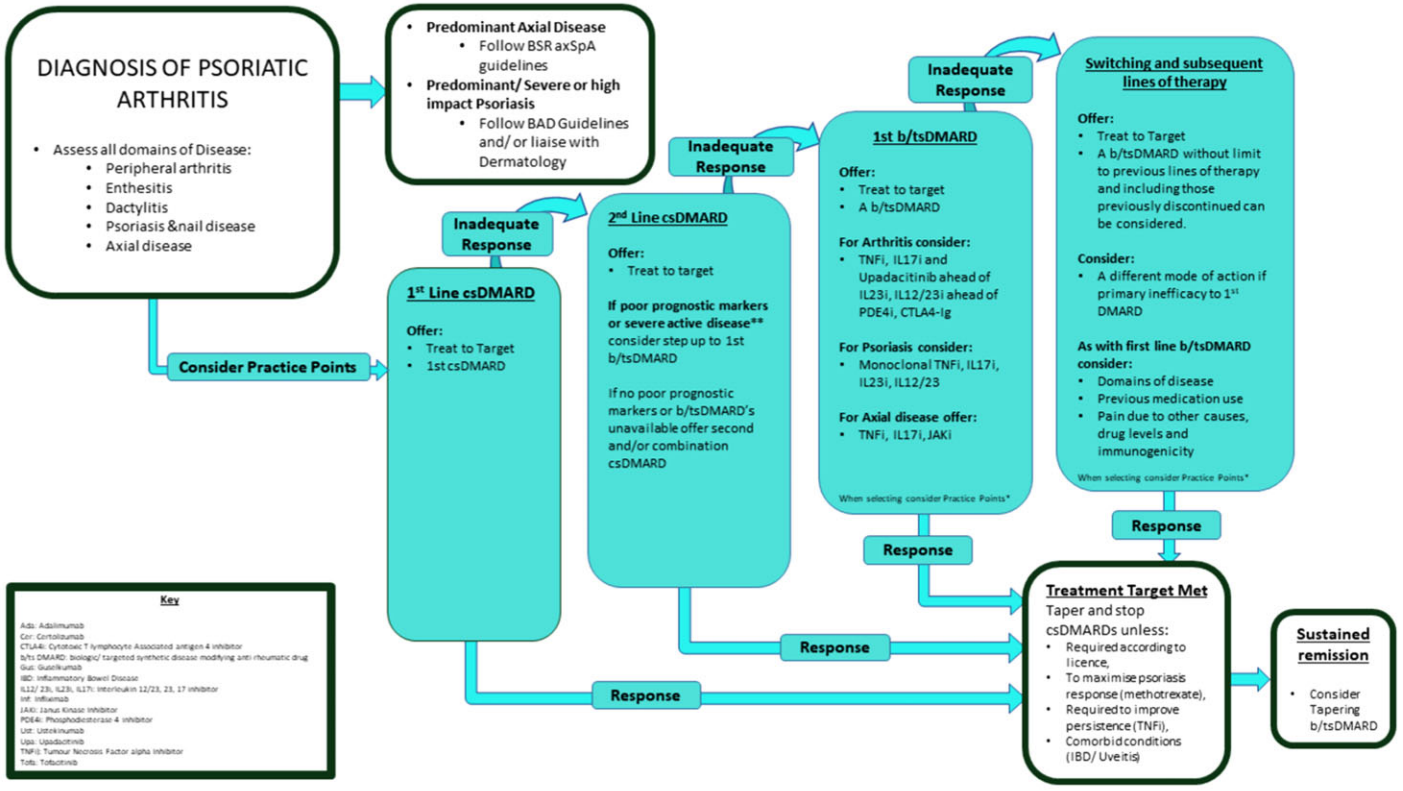
FIG. 1 Summary algorithm for the treatment of an individual with PsA with b/tsDMARDS



DIAGNOSIS OF PSORIATIC ARTHRITIS
Assess all domains of Disease:
Peripheral arthritis
Enthesitis
Dactylitis
Psoriasis &nail disease
Axial disease
Predominant Axial Disease
Follow BSR axSpA guidelines
Predominant/ Severe or high impact Psoriasis
Follow BAD Guidelines and/ or liaise with Dermatology
Consider Practice Points
1st Line csDMARD
Offer:
Treat to Target
1st csDMARD
Inadequate Response
2nd Line csDMARD
Offer:
Treat to target
If poor prognostic markers or severe active disease** consider step up to 1st b/tsDMARD
If no poor prognostic markers or b/tsDMARD's unavailable offer second and/or combination csDMARD
Inadequate Response
1st b/tsDMARD
Offer:
Treat to target
A b/tsDMARD
For Arthritis consider:
TNFi, IL17i and Upadacitinib ahead of IL23i, IL12/23i ahead of PDE4i, CTLA4-Ig
For Psoriasis consider:
Monoclonal TNFi, IL17i, IL23i, IL12/23
For Axial disease offer:
TNFi, IL17i, JAKi
When selecting consider Practice Points*
Inadequate Response
Switching and subsequent lines of therapy
Offer:
Treat to Target
A b/tsDMARD without limit to previous lines of therapy and including those previously discontinued can be considered.
Consider:
A different mode of action if primary inefficacy to 1st DMARD
As with first line b/tsDMARD consider:
Domains of disease
Previous medication use
Pain due to other causes, drug levels and immunogenicity
When selecting consider Practice Points*
Response
Response
Response
Response
Treatment Target Met
Taper and stop csDMARDs unless:
Required according to licence,
To maximise psoriasis response (methotrexate),
Required to improve persistence (TNFi),
Comorbid conditions (IBD/ Uveitis)
Sustained remission
Consider Tapering b/tsDMARD
Key
Ada: Adalimumab
Cer: Certolizumab
CTLA4: Cytotoxic T lymphocyte Associated antigen 4 inhibitor
b/ts DMARD: biologic/ targeted synthetic disease modifying anti rheumatic drug
Gus: Guselkumab
IBD: Inflammatory Bowel Disease
IL12/ 23i, IL23i, IL17i: Interleukin 12/23, 23, 17 inhibitor
Inf: Infliximab
JAKi: Janus Kinase inhibitor
PDE4i: Phosphodiesterase 4 inhibitor
Ust: Ustekinumab
Upa: Upadacitinib
TNFi: Tumour Necrosis Factor alpha inhibitor
Tofa: Tofacitinib

Practice Points*

i)Select b/tsDMARDS typically based on PsA phenotype and comorbidities:
- If moderate/ severe or recurrent uveitis consider Adalimumab or monoclonal TNFi
- If CD offer Ada, Inf, Cer, Ust, Consider Gus.
- If UC Offer Ada, Inf, Gol, Ust, Tofa, Consider Upa.

ii) Concomitant csDMARDS
- Concomitant csDMARDS are not routinely required to improve efficacy (except Tofacitinib).
- Consider concomitant csDMARDS to maximise skin response (methotrexate), improve persistence (with TNFi) or for comorbidity (ie IBD/ Uveitis)

iii) Consider signposting to weight loss and smoking cessation interventions if required to improve drug persistence/ disease activity

iv) Where multiple modes of action are equally clinically appropriate cost of treatment should be taken in to consideration

v) **Defined as at least three tender and three swollen joints or those with fewer joints and either poor prognostic markers or severe disease impact defined as ≥2 domains involved, extraarticular involvement or impaired quality of life

Downloaded from https://academic.oup.com/rheumatology/article/61/9/e255/6594139 by guest on 03 February 2023

ii. In people with active peripheral psoriatic arthritis, with inadequate response or intolerance to csDMARDs, offer a bDMARD (TNFi, IL12/23i, IL-17i, IL-23i, CTLA4-Ig) or tsDMARD (JAKi, or PDE4i) (GRADE 1A, 94%). When selecting therapy, consider using TNFi, IL17i or upadacitinib (UPA) ahead of IL12/23i or IL23i ahead of PDE4i ahead of CTLA4-Ig (GRADE 2B, SoA 88%).

A summary of the results from RCTs of (b/ts)DMARDs in PsA is shown in Table 1. The data supporting the first recommendation to offer a b/tsDMARD was based on trials of medication *vs* placebo in the relevant domains of disease. There are no data to support optimal selection of drugs for individuals, but the guideline group developed a consensus recommendation to support biologic choice based on efficacy data, speed of onset and adverse events (Table 1). TNF inhibitors remain the most widely used first line biologic in PsA and none of the other therapies have shown superiority to them for articular disease. Head-to-head studies now exist for IL-17i and upadacitinib showing non-inferiority to TNFi, hence their inclusion as potential first choices. Despite a lack of head-to-head data, there were concerns that clinical responses to IL12/23i, IL23i, PDE4i and CTLA4-Ig might be slightly lower and slower than TNFi. Physicians should be aware of the MHRA safety warning around the use of tofacitinib [30]. The safety data demonstrating increased rates of venous thromboembolic disease (VTE), major cardiovascular event (MACE) and malignancy with tofacitinib compared with TNFi available at the time of writing prompted the committee to differentiate between upadacitinib and tofacitinib in the recommendation.

PsA with enthesitis

iii. In people with active psoriatic enthesitis, with inadequate response or intolerance to a csDMARD, offer any bDMARD (TNFi, IL12/23i, IL-17i, IL-23i) or tsDMARD (JAKi, or PDE4i) (GRADE 1A, SoA 91%).

PsA with dactylitis

iv. In people with active psoriatic dactylitis, with inadequate response or intolerance to a csDMARD, offer any bDMARD (TNFi, IL12/23i, IL-17i, IL-23i) or tsDMARD (JAKi, or PDE4i) (GRADE 1A, SoA 92%).

Active enthesitis and dactylitis are seen in many PsA patients and are usually assessed clinically. Where any question exists as to the cause of pain, additional imaging (ultrasound or magnetic resonance imaging) may be helpful. Positive enthesitis and dactylitis outcomes were seen with all of the medications included in the SLR. Typically, these are as secondary outcomes in peripheral arthritis studies, although there are a small number of specific trials in enthesitis or dactylitis. Some older drugs (Table 1) did not collect these outcomes in the initial phase 3 trials and therefore have poorer quality evidence. However, the group agreed that there was no evidence of differentiation within the drug classes and so all drugs within each class are recommended equally. However, we note that the use of biologics for people with less than three tender or swollen joints is not currently permitted by NICE TAGs, which impede access to therapies for these indications.

PsA with axial disease

v. In people with active psoriatic axial disease, with inadequate response or intolerance to at least two NSAIDs, offer any TNFi or IL-17i or consider a JAKi (GRADE 1A, SoA 92%).

In the literature search, evidence of an improvement in the BASDAI was seen in people with evidence of axial manifestations within the peripheral PsA trials. However, the group noted that the BASDAI is not specific to axial disease and is heavily influenced by disease activity in other domains of PsA. There was one specific axial study in a population with PsA who had physician-reported axial manifestations, and this found evidence of a clinical and imaging benefit for an IL-17Ai (secukinumab) [31]. The group also utilized results from ankylosing spondylitis (AS) and axial spondyloarthritis (aAxSpA) trials to support the recommendations. There are positive trials for TNFi, IL-17i and JAKi in axial SpA. In contrast, there are trials for of an IL-12/23i that were stopped early, a negative trial for apremilast and a negative trial for an IL-23i. The group agreed to a practical approach, utilizing what is known from AS/AxSpA studies to support the evidence found for small subgroups in the PsA trials and the single trial in PsA where all people had axial manifestations. The evidence from the SLR supporting these recommendations can be viewed in supplementary file S1, available at *Rheumatology* online.

PsA with extra-articular manifestations (psoriasis, uveitis, inflammatory bowel disease)

vi. Where a person has associated conditions alongside their psoriatic arthritis, such as psoriasis, uveitis and/or IBD, a multidisciplinary and multispecialty approach should be taken for their care including timely discussions prior to systemic treatment changes. Be aware of other licensed indications and option for differential dosing of common medications in different indications to optimize doses for each individual (GRADE 1B, SoA 98%).

Psoriasis

vii. In the presence of psoriasis, offer concomitant topical therapy (in line with NICE CG 153) (GRADE 1A, SoA 96%).

viii. In the presence of psoriasis and/or nail psoriasis, all currently licensed b/tsDMARDs can be offered but consider prioritizing therapies recommended use for psoriasis: monoclonal TNFi, IL-17i, IL-12/23i or IL-23i summarized in publication [32] (GRADE 1A, SoA 93%).

ix. In the presence of significant [significant psoriasis is defined as extensive psoriasis (BSA $\geq$ 10 or PASI $\geq$ 10) or localised psoriasis associated with significant functional impairment and/or high levels of distress (for example severe nail disease or involvement at high-impact sites)] psoriasis, be aware that IL-17i and IL23i have superior evidence of efficacy over TNFi (GRADE 1A, SoA 92%).

The studies included in the SLR often reported psoriasis outcomes in people with 3% or more body surface area (BSA) plaque psoriasis. The SLR found a benefit for all of the bDMARDs and tsDMARDS included. In the dermatology literature, there are an increasing number of head-to-head trials comparing bDMARDs in psoriasis with evidence of superior efficacy for IL-17i and IL-23i over TNFi. However, the guideline group agreed that psoriasis tends to be less severe in rheumatology clinics and it is unlikely that such large disparities will exist in this population. Where psoriasis is more severe, then the discussion between the multidisciplinary team is important to select therapy. Further support is available in the clinical implementation toolkit developed by the British Association of Dermatologists.

Uveitis

x. In the presence of a mild relapse of anterior uveitis, follow standard treatment with concomitant topical therapy (GRADE 1A, SoA 94%).
xi. In the presence of moderate to severe sight threatening uveitis or multiple recurrent relapses, consider adalimumab or another monoclonal TNFi (GRADE 1A, SoA 97%).
xii. Refer to the global consensus guideline [33] or NHS England guideline [34] for additional advice on management of uveitis (GRADE 1C, SoA 96%).

There is little evidence for the management of uveitis specifically in people with psoriatic arthritis but there are many trials in wider populations of either people with uveitis or those with uveitis and spondyloarthritis. The guideline group therefore considered evidence from this wider population within existing ophthalmology guidelines and pathways. The evidence from the SLR supporting these recommendations can be viewed in supplementary file S2, available at *Rheumatology* online.

IBD

xiii. In the presence of suspected relapse of IBD, discuss with gastroenterology as a first step (GRADE 1C, SoA 94%).
xiv. In the presence of moderate to severe Crohn's disease, offer any of adalimumab, infliximab, certolizumab, ustekinumab or consider IL-23i (GRADE 1A, SoA 93%).
xv. In the presence of moderate to severe UC, offer any of adalimumab, infliximab, golimumab, ustekinumab or tofacitinib, or consider upadacitinib (GRADE 1A, SoA 93%).
xvi. Prior to prescription of an IL-17i, consider GI referral for people with un-investigated persistent lower GI symptoms or people with a strong family history of IBD (GRADE 2C, SoA 93%).
xvii. Do not use IL-17i in people with active Crohn's disease (GRADE 1B, SoA 88%).
xviii. IBD is not an absolute contraindication to commencement of an IL17i; however, secukinumab and ixekizumab are not recommended in individuals with IBD. Exercise caution and consult gastroenterology team before offering IL-17i to people with controlled UC or Crohn's disease. If used, individuals and their clinicians should be regularly monitoring for symptoms compatible with IBD (GRADE 1C, SoA 89%).

As for uveitis, there was no evidence to support the literature search specific to people with PsA and IBD. This guideline therefore considered evidence for relevant bDMARDs and tsDMARDs in trials of people with IBD to allow rheumatologists to understand their effectiveness. Conditional recommendations are included where recent evidence support efficacy in a phase 3 trial. The evidence for the adverse IBD effects of IL-17i has led to a cautious approach in this guideline. They are not universally excluded but should only be prescribed where other possible options have failed, and the person has well-controlled IBD. Further information is available in guidelines published by the British Society of Gastroenterology [35] and the European Crohn's and Colitis Organisation [36]. The evidence from the SLR supporting these recommendations can be viewed in supplementary file S3, available at *Rheumatology* online.

Treatment strategy

xix. A treat-to-target strategy, whereby an individual's disease activity is proactively measured and treatment escalated accordingly, should be offered to all people with psoriatic arthritis who require treatment (GRADE 1A, SoA 96%).
xx. The treat-to-target strategy should aim for remission or alternatively low disease activity, taking into account patient goals, associated conditions and co-morbidities, and non-inflammatory causes of pain (GRADE 1B, SoA 96%).

The evidence from the TICOPA trial indicated that a treat-to-target strategy was effective across a range of disease domains and this was supported by the group's own experiences. Therefore, a recommendation was made to offer this strategy to people with PsA utilizing regular and validated measurements of disease activity. A second recommendation was made based on consensus in the group that limiting the target to a single measure did not account for the totality of the disease effects. Therefore, the group recommended a disease activity target while also indicating that physicians should consider the patient goals they established early in the

Downloaded from https://academic.oup.com/rheumatology/article/61/9/e255/6594139 by guest on 03 February 2023

process, a person's co-morbidities, and other possible causes of pain. Incorporating this approach would keep the person's experiences at the centre of the care. Further advice on treat-to-target in PsA is available in specific international recommendations [16]. The evidence from the SLR supporting these recommendations can be viewed in supplementary file S4, available at *Rheumatology* online.

xxi. In people with psoriatic arthritis who are on treatment and in a stable low disease activity state across disease domains and associated conditions, consider dose reduction or dose spacing of medication following shared decision making with the patient and in consultation with the other specialists involved in their care (GRADE 2B, SoA 98%).

The literature search identified one RCT of treatment withdrawal involving 17 people with PsA and was graded as low quality. However, the clinicians on the guideline group all indicated that they utilized some form of dose tapering in some cases within their usual practice. Given that many bDMARDs and tsDMARDs have standard doses, this is often done by stretching out the interval between doses, e.g. taking adalimumab 40 mg every 3 weeks. Shared decision making is thought to be very important for this process. People should not be forced to taper if they are unwilling as the evidence for a benefit is not strong enough. If considering tapering, there should be meaningful involvement of all the specialists involved in the care of an individual in this decision. The evidence from the SLR supporting these recommendations can be viewed in supplementary file S5, available at *Rheumatology* online.

Prescribing/switching

xxii. When considering treatment with biosimilars for people with PsA, refer to the British Society for Rheumatology 2018 factsheet on biosimilars [37] (GRADE 1C, SoA 96%).

xxiii. In people with active psoriatic arthritis beginning b/tsDMARDs, the routine use of concurrent csDMARDs is not required but concurrent csDMARDs may be required for the drug licence and may be considered to maximize effectiveness for skin disease, IBD or uveitis and/or to improve persistence with TNFi (GRADE 1A, SoA 97%).

xxiv. In people with active psoriatic arthritis, with inadequate response or intolerance to a b/tsDMARD, offer any of the current licensed b/tsDMARD treatments (GRADE 1A, SoA 94%).

xxv. When selecting therapies, following an inadequate response or intolerance to a b/tsDMARD, consider the following (GRADE 2B, SoA 96%):
   a. the domains of disease relevant in that individual, previous medication use, and associated conditions such as psoriasis, uveitis, and IBD, as with first-line b/tsDMARDS;
   b. in people who have primary inefficacy to a b/tsDMARD, consider a different mode of action for the next treatment; and
   c. in people who have developed secondary inefficacy to a b/tsDMARD, consider drugs with the same mode of action first; however, all currently licenced b/tsDMARDS, without limit to previous lines of therapy and including those previously discontinued can be considered.

Large-scale switches to biosimilar medications have occurred and continue to occur as more biosimilar medications become available. These are decisions rooted in finance rather than formal efficacy and there is very little evidence for or against switching. This guideline is utilizing the recommendations held within the 2018 BSR factsheet on biosimilars. It is a consensus document and among its key recommendations it states that people should be offered the most cost-effective biologic medications, encouraging shared decision-making and integration of the wider treatment group in decision-making, and not undertaking sequential switching. The guideline recommends that people can switch back to the originator if they lose efficacy or there are safety issues with the new biosimilar. The evidence from the SLR supporting these recommendations can be viewed in supplementary file S6, available at *Rheumatology* online.

One RCT and two observational studies related to concurrent use of csDMARDs were identified in the literature search. All of these studied TNF inhibitors and indicated that there was no clinically important benefit for the routine use of csDMARDs. However, the group discussed other data outside the SLR particularly related to longevity of medications in national biologics registries. The group also raised the issue of csDMARD use for other indications such as psoriasis or related SpA conditions. The evidence from the SLR supporting these recommendations can be viewed in supplementary file S7, available at *Rheumatology* online.

Lack or loss of response to advanced therapies is a relatively common problem in PsA. While there are an increasing number of trials addressing efficacy of treatments in populations who are TNFi experienced, there is little evidence to guide optimal therapy selection for individuals. There are no studies looking at efficacy in people who have lost response to drugs with other modes of action. Therefore, no specific treatment class recommendations are made. Generally, the guideline group felt that after primary inefficacy to a particular drug, it would not make sense to try another drug from the same class, but an alternative mode of action should usually be selected in the first instance, reserving them for future lines of therapy. In contrast, after secondary inefficacy the same mode of action may be the most effective treatment. However, further studies around treatment sequencing are urgently needed to guide this approach. Pending data to the contrary the committee felt that all licenced b/tsDMARDS, without limit to previous lines of therapy, including those previously discontinued should

Downloaded from https://academic.oup.com/rheumatology/article/61/9/e255/6594139 by guest on 03 February 2023

remain available as treatment options. The evidence from the SLR supporting these recommendations can be viewed in supplementary file S8, available at *Rheumatology* online.

Lifestyle choices

xxvi. People with PsA should have their height, weight and BMI recorded (GRADE 2B, 94%). In people with PsA who are overweight or obese, offer weight loss support and signpost to relevant services to maximize response and long-term medication effectiveness of biologics and targeted synthetic DMARDs (GRADE 1A, SoA 98%).

xxvii. In people with PsA, treatment selection should not be affected by a person's weight (GRADE 2C, SoA 88%).

The SLR showed similar efficacy for the medications *vs* placebo, but there were not enough data to differentiate between treatments. Therefore, the group agreed that treatment options for overweight/obese adults with PsA were identical to those offered to the general PsA population. In obese individuals, clinicians should prescribe the appropriate dose for any medication with weight-based dosing (e.g. infliximab, golimumab). It is important to note that people with PsA who are overweight/obese outnumber those of normal weight in the trials reviewed in the literature, so the data contain significant representation from this group. In the SLR, there were no studies addressing weight loss, but the group were aware of additional studies examining the benefits of weight loss in PsA. In both cases they broadly indicated a benefit of weight loss in the population [38, 39]. The group agreed weight loss is an issue that the clinical team should raise with people with PsA where required. This is due to an understanding that being overweight or obese has a negative impact on disease severity and is thought to lessen the efficacy of treatment. It is also known to be linked to more general medical problems such as metabolic syndrome and depression. There is a key role for other specialities and allied health professionals including dieticians, physiotherapists, occupational therapists and podiatrists in supporting interventions around diet and exercise/activity for people who are overweight. The evidence from the SLR supporting these recommendations can be viewed in supplementary files S9 and S10, available at *Rheumatology* online.

xxviii. People with PsA should have their smoking status recorded (GRADE 2B, SoA 97%).

xxix. In people with PsA who are smokers, signpost to smoking cessation support services to maximize treatment response, persistence and improve general health (GRADE 1A, SoA 99%).

xxx. In people with PsA, treatment selection should not be affected by the person's smoking status although doses should be adjusted appropriately (GRADE 2C, SoA 96%).

There was little clinical effectiveness evidence for b/tsDMARDs comparing smokers and non-smokers so no recommendation was made prioritizing any b/tsDMARD treatment over another. For general health benefits, particularly in people with PsA who often have other risk factors for cardiovascular disease, appropriate smoking cessation support was recommended. The evidence from the SLR supporting these recommendations can be viewed in supplementary files S11 and S12, available at *Rheumatology* online.

Applicability and utility

This guideline represents a framework to support clinicians prescribing bDMARDs and tsDMARDs for psoriatic arthritis. As in all guidelines, we recognize that individual patient circumstances will have an important influence on clinical decision-making and clinicians should continue to implement shared care approaches alongside their patients. Failure to adhere to this guideline should not necessarily be considered negligent, nor should adherence to these recommendations constitute a defence against a claim of negligence.

As in other BSR guidelines, we recommend that biologic or tsDMARD initiation should only take place under the supervision of a rheumatologist. This guideline does make recommendations on widening access to bDMARDs and tsDMARDs beyond the scope of current NICE TAGs. We recognise that currently this may not be possible to implement, but believe that our recommendations are evidence-based.

Audit tool

A model audit tool is available via the BSR website and in supplementary material S13, available at *Rheumatology* online.

Summary and conclusions

Since 2012, there has been a rapid expansion in the advanced therapies licensed for the treatment of PsA. While this is clearly of benefit to people with PsA, it does bring additional challenges for clinicians in selecting the best therapy for individuals. This guideline aims to provide practical support to rheumatology clinicians to support the prescription of bDMARDs and tsDMARDs in PsA.

Acknowledgements

We gratefully acknowledge the Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) and the members of their Treatment Recommendations working group who shared extracted data on treatment RCTs for this project.

Funding: No specific funding was received from any bodies in the public, commercial or not-for-profit sectors to carry out the work described in this manuscript. Expenses for travel were paid by the British Society for Rheumatology.

Disclosure statement: L.C.C. has received honoraria for consultation and educational talks from AbbVie, Amgen, Biogen, Boehringer Ingelheim, Bristol Myers Squibb, Celgene, Galapagos, Gilead, GSK, Janssen, Eli Lilly, Medac, Moonlake, Novartis, Pfizer and UCB. L.C.C. is also actively involved in studies evaluating new drugs for PsA; these were only included in the guideline if identified in the systematic literature review. W.T. has received research grant income from Eli Lilly and Janssen, as well as consultancy fees, speaker fees or financial support to attend conferences from Amgen, Eli Lilly, Janssen, Novartis, UCB. D.C. is the Chief Executive of Psoriasis and Psoriatic Arthritis Alliance. A.D. has acted as a consultant for Janssen, Novartis, Roche and AbbVie. A.D. is also the Director of the UCL Institute of Ophthalmology and has received funding from NIHR to start a trial on adalimumab in uveitis. A.F. has received educational support to attend conferences from or acted as a consultant or speaker for AbbVie, Almirall, Celgene, Eli Lilly, Leo Pharma, Novartis, Pfizer, Janssen and UCB. N.G. has participated in advisory boards for AbbVie, Eli Lilly, Janssen, Novartis and UCB, and is a trustee of British Psoriatic Arthritis Consortium Clinical Trials, working with Abbvie, Eli Lilly, Gilead and Novartis. P.H. has received grants and research support from Novartis, and honoraria or consultation fees from Pfizer, Eli Lilly, Janssen and Celgene. D.J. has acted as a Principal/Chief Investigator on industry-sponsored clinical trials, and has received research, development and/or education grants from Pfizer, AbbVie, Eli Lilly, Biogen, GSK, Celgene, Novartis, Gilead, UCB, Janssen, Celltrion and Sandoz. Education grants have been paid to Spondyloarthritis Training and Education (SPATE) UK Ltd, of which D.J. is a Co-Director. D.J. has received speaker fees for advisory boards/consultancy fees from Novartis, Eli Lilly, Gilead, Biogen, UCB, Janssen, AbbVie, Roche, Pfizer and Sandoz. D.J. is also a trustee to Cambridge Arthritis Research Endeavour (CARE) and British Psoriatic Arthritis Consortium (Brit-PACT), as well as a Research Steering Committee member for GRAPPA and a member of the Association for Assessment of Axial Spondyloarthritis (ASAS). G.J. is Chief Investigator of the British Society for Rheumatology Psoriatic Arthritis Register, for which the University of Aberdeen has received research grants from the British Society for Rheumatology and, in turn, Amgen. The University of Aberdeen has also received grant income from GSK for a project on which G.J. is a co-investigator. S.K. has received honoraria from Novartis and Celltrium. T.R. has received speaker or consultancy fees from AbbVie, Janssen, Novartis and UCB, as well as research grants from AbbVie, Amgen, BMS, Boehringer-Ingelheim, GSK, Janssen, Lilly, Novartis and UCB. T.R. is a trustee and executive steering group member for Brit-PACT and BRITSpA and is Chair of the Versus Arthritis Adult Inflammatory Arthritis Research Advisory Group. C.S. is GSTT-PI/co-investigator on clinical trial work or studies sponsored or supported by AbbVie, GSK, Janssen, Novartis, Pfizer, Regeneron, Roche, Boehringer Ingleheim, NIHR and SOBI. C.S. also works on PSORT and BIOMAP, which have multiple industry partners including: AbbVie, Sanquin, Qiagen, Pfizer, Novartis, MedImmune, Janssen, Celgene, Sanofi, LEO Pharma, Boehringer Ingleheim and UBC (list not exhaustive as partners change, please see psort.org and https://www.biomap-imi.eu/ for current information). C.S. is also a NICE expert advisor on interventions in psoriasis and eczema for STAs; Chair and committee member for multiple guidelines from the British Association of Dermatologists; member of the International Psoriasis Council. L.C.C. is an NIHR Clinician Scientist funded by a National Institute for Health Research Clinician Scientist award. The work was supported by the National Institute for Health Research (NIHR) Oxford Biomedical Research Centre (BRC). The views expressed are those of the author(s) and not necessarily those of the NHS, the NIHR or the Department of Health. The remaining authors have declared no conflicts of interest.

Crow,[33] László Czirják,[34] Andrea Doria,[35] Winfried Graninger,[36] Bernadett Halda-Kiss,[34] Sarfaraz Hasni,[37] Peter M. Izmirly,[38] Michelle Jung,[32] Gábor Kumánovics,[34] Xavier Mariette,[39] Ivan Padjen,[29] José M. Pego-Reigosa,[40] Juanita Romero-Diaz,[41] Íñigo Rúa-Figueroa Fernández,[42] Raphaèle Seror,[30] Georg H. Stummvoll,[43] Yoshiya Tanaka,[44] Maria G. Tektonidou,[45] Carlos Vasconcelos,[46] Edward M. Vital,[47] Daniel J. Wallace,[48] Sule Yavuz,[49] Pier Luigi Meroni,[50] Marvin J. Fritzler,[32] Ray Naden,[51] Thomas Dörner,[17] and Sindhu R. Johnson[52]

This criteria set has been approved by the European League Against Rheumatism (EULAR) Executive Committee and the American College of Rheumatology (ACR) Board of Directors. This signifies that the criteria set has been quantitatively validated using patient data, and it has undergone validation based on an independent data set. All EULAR/ACR-approved criteria sets are expected to undergo intermittent updates.

The ACR is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To develop new classification criteria for systemic lupus erythematosus (SLE) jointly supported by the European League Against Rheumatism (EULAR) and the American College of Rheumatology (ACR).

Methods. This international initiative had four phases. 1) Evaluation of antinuclear antibody (ANA) as an entry criterion through systematic review and meta-regression of the literature and criteria generation through an international Delphi exercise, an early patient cohort, and a patient survey. 2) Criteria reduction by Delphi and nominal group technique exercises. 3) Criteria definition and weighting based on criterion performance and on results of a multi-criteria decision analysis. 4) Refinement of weights and threshold scores in a new derivation cohort of 1,001 subjects and validation compared with previous criteria in a new validation cohort of 1,270 subjects.

Results. The 2019 EULAR/ACR classification criteria for SLE include positive ANA at least once as obligatory entry criterion; followed by additive weighted criteria grouped in 7 clinical (constitutional, hematologic, neuropsychiatric, mucocutaneous, serosal, musculoskeletal, renal) and 3 immunologic (antiphospholipid antibodies, complement proteins, SLE-specific antibodies) domains, and weighted from 2 to 10. Patients accumulating ≥10 points are classified. In the validation cohort, the new criteria had a sensitivity of 96.1% and specificity of 93.4%, compared with 82.8% sensitivity and 93.4% specificity of the ACR 1997 and 96.7% sensitivity and 83.7% specificity of the Systemic Lupus International Collaborating Clinics 2012 criteria.

Conclusion. These new classification criteria were developed using rigorous methodology with multidisciplinary and international input, and have excellent sensitivity and specificity. Use of ANA entry criterion, hierarchically clustered, and weighted criteria reflects current thinking about SLE and provides an improved foundation for SLE research.

INTRODUCTION

Systemic lupus erythematosus (SLE) is a complex autoimmune disease with variable clinical features (1,2). SLE manifestations are associated with multiple autoantibodies, ensuing immune complex formation and deposition, and other immune processes (2,3). This complex clinical presentation and pathogenesis makes SLE a difficult disease to grasp and define. Classification criteria are essential for the identification of relatively homogeneous groups of patients for inclusion in research studies and trials (4,5). The 1982 revised American College of Rheumatology (ACR) SLE classification criteria (6) and their 1997 revision (7) have been used worldwide. Since then, our understanding of the disease has advanced. Additional specific skin manifestations were described, some clinical symptoms were better understood, and immunologic tests, such as diminished levels of serum complement components C3 and C4 or testing for anti–β_2-glycoprotein I antibodies, entered routine clinical practice. Better understanding of organ system involvement, such as mucocutaneous abnormalities, led to questions about whether some of the independently counted criteria were in fact manifestations of the same phenomenon (8).

The 2012 Systemic Lupus International Collaborating Clinics (SLICC) classification criteria addressed many of these issues (9). Mucocutaneous and neuropsychiatric manifestations were added, as were hypocomplementemia and new antiphospholipid antibody tests; and criteria definitions were refined. The SLICC criteria emphasized that SLE is primarily an autoantibody disease, requiring at least one immunologic criterion to be present, and

Submitted for publication November 25, 2018; accepted in revised form May 1, 2019.

categorized histology-proven nephritis compatible with SLE as sufficient for classification, if antinuclear antibodies (ANAs) or antibodies to double-stranded DNA (dsDNA) were present. While achieving their goal of increasing sensitivity, the SLICC criteria have lower specificity than the 1997 ACR criteria (9,10).

Existing SLE classification criteria perform better in patients with longstanding disease than in new-onset SLE (11), and there is an increasing recognition and demand that subjects with early SLE should be included in clinical studies and trials. We therefore attempted to enrich our sample populations for early SLE in several phases of the project.

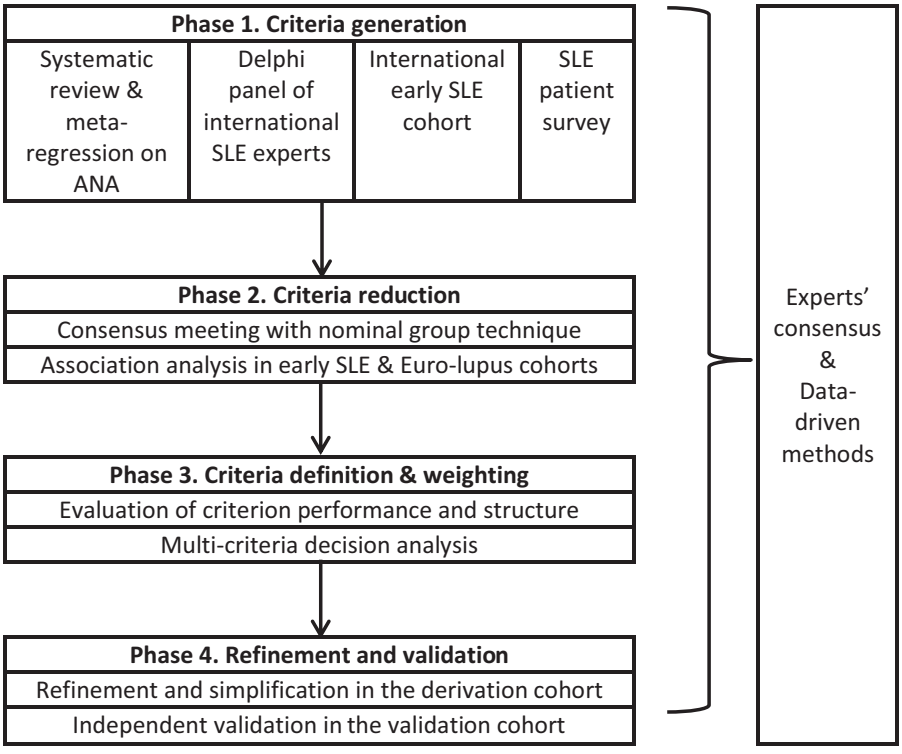
In parallel with improved understanding of SLE, the field of classification criteria development has also seen advances (4,12–14). In order to minimize investigator bias, it is now recommended that the cohorts in which the criteria are tested are from independent centers (4). Other methodologic recommendations include a balanced use of both expert-based and data-driven methods, and inclusion of the patient perspective (13,14). The approach chosen for these 2019 European League Against Rheumatism (EULAR)/ACR SLE classification criteria was specifically designed to maintain this balance and to uphold rigorous methodology.

METHODS

Methodologic overview. Using a methodologic approach based on measurement science the criteria were developed in four phases (10): 1) criteria generation, 2) criteria reduction, 3) criteria definition and weighting, and 4) refinement and validation (Figure 1). The whole initiative was overseen by a 12-member steering committee (MA, KHC, DID, MM, RR-G, JSS, DW, DTB, DLK, DJ, TD, and SRJ) nominated by EULAR and the ACR in equal numbers, based on SLE and/or methodologic experience and previous involvement in international projects.

The current project, jointly supported by the EULAR and the ACR, was originally based on two key concepts. One, we hypothesized that the presence of ANA would be better employed as an entry criterion than as a classification criterion (10). Such an approach was thought to reflect underlying SLE pathogenesis, and take into account ANA test characteristics of high sensitivity and limited specificity. Two, we expected individual criteria would not be of equal utility (weight) for the classification of SLE (15), for example, mucosal ulcers versus biopsy-proven lupus nephritis. Accordingly, the validity of using positive ANA as an entry criterion was explicitly addressed in phase I of the current activity (16). Likewise, methodologic strategies to develop weighted criteria were used.

Phase I: Criteria generation. The purpose of phase I was to test ANA as a potential entry criterion and identify candidate criteria that should be considered for SLE classification using both data-based and expert-based methods, including the patient perspective. *Phase Ia* comprised a systematic literature review of Medline, Embase, and the Cochrane databases with meta-regression to evaluate the operating characteristics of ANA testing for consideration as an entry criterion (16). *Phase Ib* consisted of a Delphi exercise of international SLE experts from the Americas, Europe, and Asia (17). These experts included



Phase 1. Criteria generation
Systematic review & meta-regression on ANA
Delphi panel of international SLE experts
International early SLE cohort
SLE patient survey
Phase 2. Criteria reduction
Consensus meeting with nominal group technique
Association analysis in early SLE & Euro-lupus cohorts
Phase 3. Criteria definition & weighting
Evaluation of criterion performance and structure
Multi-criteria decision analysis
Phase 4. Refinement and validation
Refinement and simplification in the derivation cohort
Independent validation in the validation cohort
Experts' consensus & Data-driven methods

Figure 1. Development and validation of systemic lupus erythematosus (SLE) classification criteria. ANA = antinuclear antibody.

rheumatologists, dermatologists, nephrologists, pediatricians, and non-clinical SLE researchers, providing a broad perspective. The Delphi participants were asked to nominate a broad set of items potentially useful in the classification of SLE (17). In rounds 2 and 3, participants rated the items from 1 (not at all appropriate) to 9 (completely appropriate) for classification of SLE. Criteria were retained if they reached a median rating of ≥6.5; that is, at least 50% of the ratings in the high range (7, 8, or 9). Participants were also asked about the importance of ANA and histopathology for classification of SLE. *Phase Ic* established an international cohort of patients with early SLE or conditions mimicking SLE to identify criteria that may discriminate subjects with early (less than 12 months) disease (18). *Phase Id* comprised a cross-sectional survey of SLE patients, administered via the quarterly journal of the German SLE patient organization, which asked about symptoms within 1 year before and after the patient's diagnosis of SLE (19). While at a risk of recall bias and not necessarily representative of other regions worldwide, this survey was done to explicitly take a patient standpoint into account.

For phases II and III, additional renowned European and North American SLE experts were nominated by the steering committee and invited to participate.

Phase II: Criteria reduction. *Phase IIa.* The objective of this phase was to select a set of criteria from phase I that maximized the likelihood of accurate classification of SLE, particularly of early disease. An independent panel of seven of the international SLE experts (RC, NC-C, DDG, BHH, FH, EM, and JS-G) ranked the candidate criteria from phase I. A consensus meeting of 19 international SLE experts (n = 7 nominal group technique [NGT] experts + steering committee + DK [moderator]) using NGT was conducted to reduce the list of criteria (20). Data for each candidate criterion were reviewed and discussed until consensus was achieved. The NGT experts voted on items to be retained.

Phase IIb. NGT participants pointed out that some criteria could be correlated. With the idea of potentially clustering criteria into domains, associations between candidate criteria were evaluated separately in two cohorts, the phase Ic early SLE and the Euro-lupus cohorts (21).

Phase III: Criteria definition and weighting. *Phase IIIa.* The operating characteristics of the retained candidate criteria were evaluated by literature review. Candidate criteria were hierarchically organized into clinical and immunologic domains, and definitions for the candidate criteria were iteratively refined. SLE patient advocates participated in the review of data and the steering committee discussions (22).

Phase IIIb. One hundred sixty-four case vignettes reflecting broad SLE clinical presentation were sampled from SLE centers across several countries. A panel of six of the international experts not involved in earlier phases of the project (BD, SJ, WJM, GR-I, MS, and MBU) and 11 members of the steering committee assessed and ranked a representative sample of the cases. Subsequently, at a face-to-face meeting, this panel of 17 international SLE experts iteratively compared pairs of criteria, using multicriteria decision analysis facilitated by 1000Minds software (23). The panel unanimously agreed to further reduce the list of criteria. Based on the results, provisional criteria weights were assigned and a provisional threshold score for classification was determined as the lowest score at which the expert panel had achieved consensus on classifying a case vignette as SLE (24).

Phase IV: Refinement and validation. International SLE experts not involved in phase II or phase III panels were asked to contribute cases diagnosed as SLE and controls with conditions mimicking SLE sampled from patients evaluated at their centers. Each center was asked to contribute up to 100 cases and an equal number of controls, preferentially sampling those with early disease, and regardless of their specific clinical or immunologic manifestations. Pseudonymized data on the criteria were collected using a standardized data collection form. Ethics committee approval and informed consent were obtained as per local requirements. The status ("SLE" or not) of each case underwent independent adjudication by three of four SLE experts (GB, BFH, NL, and CT) from different centers. Queries were sent back to the submitting investigator for clarification. Of this cohort, 501 SLE and 500 control subjects were randomly selected to comprise the derivation cohort, while the remaining 696 SLE and 574 control subjects formed the validation cohort.

Refinement. The performance of the draft criteria set was iteratively tested in the derivation cohort. A data-driven threshold for classification was determined by receiver operating characteristics (ROC) analysis and compared with the provisional expert-based consensus threshold. The data of SLE subjects below the threshold (misclassified) were reviewed for groups of patients with unequivocal SLE who still missed classification, and criteria weights adjusted slightly, while preserving the weighting hierarchy (details below in Results, Phase IV section). Sensitivity and specificity were tested against the ACR 1997 and the SLICC 2012 criteria. In addition, ANA as an entry criterion was tested against not having an entry criterion. Finally, the criteria weights were simplified to whole numbers. Refinements to the criteria set were presented to the steering committee and phase III expert panel, and unanimously endorsed.

Validation. The sensitivity and specificity of the final criteria were tested in the validation cohort and compared with previous SLE criteria sets.

Statistical analysis. Descriptive statistics were used to summarize the data. Confidence intervals (CIs) were calculated using the bias-corrected and accelerated bootstrap method (BCa

method) with B = 2000 bootstrap samples. The BCa method resamples the input data B times (with replacement) and calculates the required statistics (sensitivity, specificity, AUC). Based on the B bootstraps samples, the bias-correction is applied and the associated 95% CIs for the statistics are estimated. The BCa method has proven to yield very accurate coverage of estimated CIs (25). The number B of bootstrap resamples is recommended to be at least B = 1,000. We have chosen B = 2,000 and additionally checked if B = 5,000 bootstraps changed the estimated confidence bounds, which was not the case. Statistical analyses were performed using R, v.3.4.0 (The R Foundation of Statistical Computing).

RESULTS

Phase I: Criteria generation. *Phase Ia: ANA as an entry criterion.* A systematic review of Medline, Embase, and the Cochrane database identified 13,080 patients from 64 studies reporting ANA by immunofluorescence on HEp-2 cells. Meta-regression of the operating characteristics of ANA found a sensitivity of 97.8% (95% CI 96.8–98.5%) for ANA of ≥1:80, supporting use of ANA as an entry criterion (16). Since some SLE centers do not have access to HEp-2 ANA, and in view of ongoing work on the standardization of serology and potential future advances in the field, the steering committee and additional autoantibody consultants (MJF and PLM) recommended the provision "or an equivalent positive ANA test. Testing by immunofluorescence on HEp-2 cells or a solid-phase ANA screening immunoassay with at least equivalent performance is highly recommended."

Phase Ib: Delphi exercise. One hundred forty-seven international SLE experts nominated 145 candidate criteria (17). By rating the appropriateness for SLE classification, the participants in the second and third Delphi rounds reduced the list to 40 candidate criteria (Supplementary Table 1, on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.40930/abstract).

Phase Ic: International early SLE cohort. The cohort comprised 616 subjects who had been referred for possible SLE with a disease duration of less than 1 year (n = 389 early SLE and n = 227 mimicking diseases) from North America, Europe, Asia, and South America (18). In addition to supporting many of the 40 candidate criteria derived from the Delphi exercise, the comparison between early SLE and non-SLE patients showed that fever occurred more frequently (34.5% versus 13.7%; $P < 0.001$) in SLE, while SLE patients less commonly suffered from arthralgias (20.3% versus 42.7%; $P = 0.001$) and fatigue (28.3% versus 37%; $P = 0.02$).

Phase Id: Patient survey. Three hundred thirty-nine SLE patients (>99% Caucasian, 93% female) responded to the survey (19). More than half of these patients reported mucocutaneous findings in the first year of their disease (Supplementary Table 1, http://onlinelibrary.wiley.com/doi/10.1002/art.40930/abstract), but also fatigue (89%), joint pain (87%), and fever (54%) (19). Given that these items were highlighted both in the early SLE cohort and the patient survey, fever, fatigue, and arthralgias were forwarded to the next phase in addition to the 40 Delphi items. Accordingly, phases Ia–Id resulted in a total of 43 candidate criteria for consideration (Supplementary Table 1).

Phase II: Criteria reduction. *Phase IIa.* The expert panel NGT exercise reduced the candidate criteria from 43 to 21 (26). The panel distinguished potential "entry criteria," which would be required for classification, from potential "additive criteria." They endorsed "positive ANA (≥1:80 by HEp-2 immunofluorescence)" as an entry criterion. The 20 remaining additive criteria included: lupus nephritis by renal biopsy, autoantibodies, cytopenias, fever, arthritis, serositis, mucocutaneous and neuropsychiatric manifestations (Supplementary Table 1).

Phase IIb. Associations between the candidate criteria were evaluated in 389 subjects in the early SLE cohort and the 1,000 SLE subjects of the Euro-lupus cohort. Modest statistically significant correlations were limited to the mucocutaneous (r = 0.22–0.30), neurologic (r = 0.22), and immunologic (r = 0.33) domains in the early SLE cohort, and this modest correlation was replicated in the Euro-lupus cohort (21). Given these associations, criteria were clustered within domains, so that only 1 criterion within each domain would be counted.

Phase III: Criteria definition and weighting. *Phase IIIa.* Based on the literature, definitions of the 20 candidate additive criteria were refined, using a data-driven evaluation of operating characteristics (22), retaining only feasible items with a prevalence of at least 1% according to literature. Literature review led to the consensus decision to evaluate 5 different candidate criteria within the neuropsychiatric domain (delirium, psychosis, seizure, mononeuropathy, cranial neuropathy) and potential separation of acute pericarditis from pleural or pericardial effusions and between diminished C3 or C4 versus diminished C3 and C4. The resulting 23 candidate criteria (Supplementary Table 1, on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.40930/abstract) were organized into 7 clinical and 3 immunologic domains, with hierarchical clustering (22). Only the highest-ranking item in each domain was to be counted. Instead of devising exclusion definitions for each criterion, the decision was made to attribute any item to SLE only if no more likely explanation was present. For leukopenia and joint involvement, it was decided to formally test alternative definitions in the derivation cohort. Given the importance of testing for antibodies, particularly for anti-dsDNA, for which tests of relatively low specificity are in use, great care was taken to precisely define testing (Table 1).

Table 1. Definitions of SLE classification criteria*

Criteria	Definition
Antinuclear antibodies (ANA)	ANA at a titer of ≥1:80 on HEp-2 cells or an equivalent positive test at least once. Testing by immunofluorescence on HEp-2 cells or a solid-phase ANA screening immunoassay with at least equivalent performance is highly recommended
Fever	Temperature >38.3°C
Leukopenia	White blood cell count <4,000/mm³
Thrombocytopenia	Platelet count <100,000/mm³
Autoimmune hemolysis	Evidence of hemolysis, such as reticulocytosis, low haptoglobin, elevated indirect bilirubin, elevated LDH, AND positive Coombs' (direct antiglobulin) test
Delirium	Characterized by 1) change in consciousness or level of arousal with reduced ability to focus, 2) symptom development over hours to <2 days, 3) symptom fluctuation throughout the day, 4) either 4a) acute/subacute change in cognition (e.g., memory deficit or disorientation), or 4b) change in behavior, mood, or affect (e.g., restlessness, reversal of sleep/wake cycle)
Psychosis	Characterized by 1) delusions and/or hallucinations without insight and 2) absence of delirium
Seizure	Primary generalized seizure or partial/focal seizure
Non-scarring alopecia	Non-scarring alopecia observed by a clinician†
Oral ulcers	Oral ulcers observed by a clinician†
Subacute cutaneous OR discoid lupus	Subacute cutaneous lupus erythematosus observed by a clinician:† Annular or papulosquamous (psoriasiform) cutaneous eruption, usually photodistributed If skin biopsy is performed, typical changes must be present (interface vacuolar dermatitis consisting of a perivascular lymphohistiocytic infiltrate, often with dermal mucin noted). OR Discoid lupus erythematosus observed by a clinician:† Erythematous-violaceous cutaneous lesions with secondary changes of atrophic scarring, dyspigmentation, often follicular hyperkeratosis/plugging (scalp), leading to scarring alopecia on the scalp If skin biopsy is performed, typical changes must be present (interface vacuolar dermatitis consisting of a perivascular and/or periappendageal lymphohistiocytic infiltrate. In the scalp, follicular keratin plugs may be seen. In longstanding lesions, mucin deposition may be noted)
Acute cutaneous lupus	Malar rash or generalized maculopapular rash observed by a clinician† If skin biopsy is performed, typical changes must be present (interface vacuolar dermatitis consisting of a perivascular lymphohistiocytic infiltrate, often with dermal mucin noted. Perivascular neutrophilic infiltrate may be present early in the course)
Pleural or pericardial effusion	Imaging evidence (such as ultrasound, x-ray, CT scan, MRI) of pleural or pericardial effusion, or both
Acute pericarditis	≥2 of 1) pericardial chest pain (typically sharp, worse with inspiration, improved by leaning forward), 2) pericardial rub, 3) EKG with new widespread ST elevation or PR depression, 4) new or worsened pericardial effusion on imaging (such as ultrasound, x-ray, CT scan, MRI)
Joint involvement	EITHER 1) synovitis involving 2 or more joints characterized by swelling or effusion OR 2) tenderness in 2 or more joints and at least 30 minutes of morning stiffness
Proteinuria >0.5 g/24 hours	Proteinuria >0.5 g/24 hours by 24-hour urine or equivalent spot urine protein-to-creatinine ratio
Class II or V lupus nephritis on renal biopsy according to ISN/RPS 2003 classification	Class II: Mesangial proliferative lupus nephritis: purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposit. A few isolated subepithelial or subendothelial deposits may be visible by immunofluorescence or electron microscopy, but not by light microscopy Class V: Membranous lupus nephritis: global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations

(Continued)

Table 1. *(Cont'd)*

Criteria	Definition
Class III or IV lupus nephritis on renal biopsy according to ISN/RPS 2003 classification	Class III: Focal lupus nephritis: active or inactive focal, segmental, or global endocapillary or extracapillary glomerulonephritis involving <50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations Class IV: Diffuse lupus nephritis: active or inactive diffuse, segmental, or global endocapillary or extracapillary glomerulonephritis involving ≥50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class includes cases with diffuse wire loop deposits but with little or no glomerular proliferation
Positive antiphospholipid antibodies	Anticardiolipin antibodies (IgA, IgG, or IgM) at medium or high titer (>40 APL, GPL, or MPL, or >the 99th percentile) or positive anti-β_2GPI antibodies (IgA, IgG, or IgM) or positive lupus anticoagulant
Low C3 OR low C4	C3 OR C4 below the lower limit of normal
Low C3 AND low C4	Both C3 AND C4 below their lower limits of normal
Anti-dsDNA antibodies OR anti-Sm antibodies	Anti-dsDNA antibodies in an immunoassay with demonstrated ≥90% specificity for SLE against relevant disease controls OR anti-Sm antibodies

* SLE = systemic lupus erythematosus; LDH = lactate dehydrogenase; CT = computed tomography; MRI = magnetic resonance imaging; EKG = electrocardiography; ISN = International Society of Nephrology; RPS = Renal Pathology Society; anti-β_2GPI = anti–β_2-glycoprotein I; anti-dsDNA = anti–double-stranded DNA.
† This may include physical examination or review of a photograph.

Phase IIIb. The 1.5-day in-person consensus meeting using multicriteria decision analysis involved 74 decisions between pairs of criteria. Criteria weights were calculated by 1000Minds software based on these decisions (Table 2). International Society of Nephrology/Renal Pathology Society class III or IV nephritis consistently attained higher weight than class II or V nephritis, so lupus nephritis by histology was separated into 2 different criteria. Class VI lupus nephritis as an end-stage manifestation was unanimously eliminated. Likewise, the experts unanimously voted to not retain mononeuropathy and cranial neuropathy, which had been included into the set of potential neuropsychiatric items in phase IIIa but turned out to add little to SLE classification. The use of weighted criteria led to a sum score that is a measure of the relative probability of a subject having SLE, with higher scores indicating higher likelihood. Experts reached full consensus on a classification of SLE at a provisional threshold score of >83 of a theoretical maximum of 305 (24).

Phase IV: Refinement and validation. Twenty-one centers from the US, Canada, Mexico, Austria, Croatia, France, Germany, Greece, Hungary, Italy, Portugal, Spain, the UK, Turkey, Hong Kong, and Japan submitted a total of 2,339 cases from their cohorts; 1,197 SLE and 1,074 non-SLE diagnoses (Table 3) were verified by 3 adjudicators blinded to the proposed classification criteria system. Due to lack of consensus during adjudication, 68 subjects (2.9%) were excluded from the analysis.

Derivation cohort. Of the 2,271 triple-adjudicated cases, 501 SLE and 500 non-SLE cases were randomly assigned to the derivation cohort. The provisional weighting system derived from phase III was tested in the derivation cohort. ROC analysis suggested a data-driven threshold of ≥70 (of a maximum of 305), with a sensitivity of 95.4% and a specificity of 95.2%, which was superior to the consensus-derived provisional threshold of >83 that had high specificity (98.8%), but lower sensitivity (81.6%). Review of subjects below the threshold of 70 identified a subgroup of SLE subjects with joint involvement and/or leukopenia. Thus, weights for leukopenia and joint involvement were each adjusted (Table 2) to reduce misclassification. When alternative definitions for leukopenia and joint involvement were tested, leukopenia defined as a white blood cell count (WBC) <4000/mm^3 at least once (9) also had a slightly higher sensitivity + specificity (1.944 versus 1.942) than leukopenia defined as WBC <4,000/mm^3 on 2 or more occasions (6,26). Joint involvement defined as EITHER "synovitis involving 2 or more joints, characterized by swelling or effusion," OR "tenderness in 2 or more joints and at least 30 minutes of morning stiffness" (9) had a higher combined sensitivity and specificity than arthritis defined simply as synovitis of 2 or more joints (1.944 versus 1.900). When retested, the revised criteria had increased sensitivity, and maintained sensitivity + specificity. Evaluating ANA as an entry criterion, the criteria with the ANA entry criterion had better performance than without (sensitivity + specificity 1.944 versus 1.930). Next, the weights were simplified by division to whole numbers to achieve a threshold of 10 (Table 2). In the derivation cohort, the sensitivity and specificity of the final criteria set (Figure 2) were reaching the performance benchmarks set for this project (Table 4).

Validation. The validation cohort, that is, the full cohort minus the derivation cohort, comprised 1,270 triple-adjudicated subjects (n = 696 SLE, n = 574 controls). The criteria, with

Table 2. Relative weights of the additive classification criteria items*

Domain	Item	Original	Modification	Revised	Simplified
Constitutional	Fever	13		13	2
Hematologic	Leukopenia	12	+7	19	3
	Thrombocytopenia	26		26	4
	Autoimmune hemolysis	28		28	4
Neuropsychiatric	Delirium	12		12	2
	Psychosis	20		20	3
	Seizure	34		34	5

	Class II/V	55		55	8
	Class III/IV	74		74	10
Antiphospholipid antibodies	Antiphospholipid	13		13	2
Complements	C3 or C4 low	19		19	3
	C3 and C4 low	27		27	4
SLE-specific antibodies	Anti-Sm	40		40	6
	Anti-dsDNA	38		38	6

* Weights derived from the phase III consensus meeting with multicriteria decisions analysis (original), added points for leukopenia and joint involvement (modification), the resulting weights (revised), and the final simplified weights (simplified). SCLE = subacute cutaneous lupus erythematosus; DLE = discoid lupus erythematosus; ACLE = acute cutaneous lupus erythematosus; SLE = systemic lupus erythematosus; anti-dsDNA = anti–double-stranded DNA.

positive ANA as an entry criterion, weighted criteria in 7 clinical domains (constitutional, hematologic, neuropsychiatric, mucocutaneous, serosal, musculoskeletal, renal) and 3 immunologic domains (antiphospholipid antibodies, low complements, anti-Sm and anti-dsDNA as SLE-specific antibodies), and a classification threshold score of ≥10 (out of a theoretical maximum of 51) (Figure 2), had a sensitivity of 96.1% and a specificity of 93.4% (Table 4). It demonstrated improved performance compared with the ACR 1997 and SLICC 2012 criteria.

DISCUSSION

New SLE classification criteria were developed with support by both the ACR and EULAR. Through a four-phase, iterative process, we have defined an additive, weighted multicriteria system that produces a measure of the relative probability that an individual can be classified as SLE. The system defines a threshold above which experts would classify cases as SLE for the purpose of research studies. We have carefully defined the criteria to improve reliability and precision, and have grouped the criteria into 10 hierarchical domains. We have validated the criteria against a large number of cases, including many patients with manifestations that resemble SLE but who do not have SLE. This approach, as well as the resulting criteria system, represents a paradigm shift for the classification of SLE.

We have defined positive ANA at any time as required entry criterion. There were three possible ways to deal with ANA testing. The previous criteria sets have treated ANA the same as the much more specific antibodies against Sm and dsDNA, which we considered suboptimal given important differences in sensitivity and specificity. We could have excluded ANA completely in classifying lupus, but we still consider ANA a useful test and concept. We therefore decided to test ANA as an entry criterion, which reflects the use of ANA as a highly sensitive screening test.

Criteria using ANA as entry criterion had better performance. During the phase I Delphi exercise, 58% of SLE experts did not feel comfortable and an additional 19% were uncertain about classifying a patient with SLE in the absence of ever having a

Table 3. Demographic characteristics of the derivation and validation cohorts*

positive ANA (17). The systematic literature review and meta-regression of data on 13,080 subjects demonstrated ANA ≥1:80 to have a sensitivity of 98% with a lower limit of the 95% CI at 97% (16). In the phase I early SLE cohort, 99.5% of the 389 SLE patients were ANA positive (18). The frequencies of ANA-positive SLE patients in the derivation and validation cohorts (99.6% and 99.3%, respectively) were in the same range. Since both in the early SLE cohort and in the derivation and validation cohorts, patients were included in many centers worldwide independent of ANA positivity, the latter data provide additional support for ANA as an entry criterion.

Using ANA as entry criterion means the new criteria cannot classify SLE among patients who are persistently ANA negative. While possibly also distinguished by lower cytokine levels (27) and lower efficacy of immunomodulatory treatment (28), such a subgroup of patients exists. Although small, it may vary in size

Entry criterion

Antinuclear antibodies (ANA) at a titer of ≥1:80 on HEp-2 cells or an equivalent positive test (ever)

↓

If absent, do not classify as SLE
If present, apply additive criteria

↓

Additive criteria

Do not count a criterion if there is a more likely explanation than SLE.
Occurrence of a criterion on at least one occasion is sufficient.
SLE classification requires at least one clinical criterion and ≥10 points.
Criteria need not occur simultaneously.
Within each domain, only the highest weighted criterion is counted toward the total score§.

Clinical domains and criteria	Weight	Immunology domains and criteria	Weight

↓

Classify as Systemic Lupus Erythematosus with a score of 10 or more if entry criterion fulfilled.

Figure 2. Classification criteria for systemic lupus erythematosus (SLE). § = additional criteria within the same domain will not be counted; * = in an assay with 90% specificity against relevant disease controls. Anti-β_2GPI = anti–β_2-glycoprotein I; anti-dsDNA = anti–double-stranded DNA.

in different populations (16). This patient subset needs to be put high on the scientific agenda for further investigation. Additional characterization of this phenomenon may lead to an alternative entry criterion for this small group of patients. For the moment, we still think it is acceptable to exclude ANA-negative patients from clinical trials.

Molecular classification criteria were also considered during the development of these criteria (29). Many novel biomarkers were

Table 4. Operating characteristics of the new classification criteria compared with the ACR 1997 and SLICC 2012 classification criteria in the derivation and the validation cohorts*

	ACR 1997 criteria	SLICC 2012 criteria	EULAR/ACR 2019 criteria
Derivation			
Sensitivity (95% CI)	0.85 (0.81–0.88)	0.97 (0.95–0.98)	0.98 (0.97–0.99)
Specificity (95% CI)	0.95 (0.93–0.97)	0.90 (0.87–0.92)	0.96 (0.95–0.98)

Validation			
Sensitivity (95% CI)	0.83 (0.80–0.85)	0.97 (0.95–0.98)	0.96 (0.95–0.98)
Specificity (95% CI)	0.93 (0.91–0.95)	0.84 (0.80–0.87)	0.93 (0.91–0.95)
Combined (95% CI)	1.76 (1.73–1.80)	1.80 (1.77–1.84)	1.90 (1.87–1.92)

* ACR = American College of Rheumatology; SLICC = Systemic Lupus International Collaborating Clinics; EULAR = European League Against Rheumatism; 95% CI = 95% confidence interval.

nominated, such as increased circulating B lymphocyte stimulator (BLyS), interferon-γ (IFNγ)–induced protein 10 kd (IP-10), monocyte chemoattractant protein 1 (MCP-1), tumor necrosis factor α (TNFα), type I IFN signature, or increased Th17 and plasma cell populations. They were all voted out in the expert Delphi exercise, largely because of limited availability in the clinical setting and/or insufficient evidence (5). However, inclusion of novel biomarkers, beyond autoantibodies, may ultimately further improve the specificity of SLE classification, increase alignment of classification with underlying disease pathogenesis, and improve the performance and information content of clinical trials. Thus, testing of biomarkers against these criteria is an important area for future research.

A new clinical criterion, unexplained fever, turned out to be common and remarkably characteristic for SLE. However, since infections are a major cause of death in SLE, it is of utmost importance to stress that fever, like all other criteria manifestations, should only be counted if no better explanation exists, and that infections have to be suspected first in any patient with (potential) SLE, particularly when C-reactive protein is elevated (30). The concept that all criteria are only to be counted if SLE is thought to be the most likely cause of the manifestation (i.e., no other more likely cause exists) is central to these new EULAR/ACR criteria, and is explicitly stated as an overarching principle. Some criteria, such as delirium, psychosis, and acute pericarditis, were in part redefined based on existing scientific definitions (22). Where alternative definitions were used, the performance of the alternative definitions was comparatively evaluated in the derivation cohort.

The differential weighting of criteria better represents their relative contribution to an individual's classification of SLE. For SLE, renal biopsy with class III or IV lupus nephritis carries the most weight and in the presence of a positive ANA is enough to classify a patient as SLE. This further develops a concept of the SLICC criteria (9) and reflects the current thinking of SLE experts; in the Delphi exercise, 85% would classify SLE on renal pathology alone (17). Renal biopsy with class II or V lupus nephritis still carries a large weight (8 points) but is not by itself sufficient for the classification of SLE.

The numerical goal of this project was to keep the specificity similar to the specificity of the ACR 1997 criteria, but increase the sensitivity to the high sensitivity level of the SLICC criteria, if possible. The validation cohort data suggest that this goal has been achieved. From our data, it appears that the SLICC criteria increase in sensitivity was to a significant degree founded in accepting renal histology and adding subacute cutaneous lupus and low complement levels. These three advances are mirrored in the current criteria. Many of the other additional symptoms of the SLICC criteria were of very low frequency. Specificity was increased by weighting of criteria, by the NGT expert panel decision to not allow lymphopenia to go forward, and, importantly, by the decision that no criterion be counted if better explained by another condition.

The new criteria provide a simple, directed, and highly accurate method for classifying SLE. An electronic "app" is in preparation, which will assist in the use of these criteria. However, it is important to stress that classification criteria are not designed for diagnosis or treatment decisions (5). They should never be used to exclude patients who do not fully meet these criteria from receiving appropriate therapies. This is also pertinent to patients with ANA-negative SLE discussed above. Diagnosis of SLE remains the purview of an appropriately trained physician evaluating an individual patient (5).

The new SLE classification system also provides new research opportunities. With much interest in early or latent SLE (31,32), the additive point system and the relative probability of classification it produces allows for systematic study of individuals who fall below the classification threshold. This will facilitate studies of disease evolution and early intervention. Furthermore, the use of an additive scoring system will allow for studying the idea of "ominousity," that is, the potential implications of having very high scores on disease severity and subsequent prognosis. This work would need to reconsider the

relative contribution of individual criteria (weights) and consider additional criteria that potentially contribute to ominousity.

It is anticipated that other groups will test these criteria, which will constitute important external validation. This will be particularly important for pediatric SLE and those with organ-dominant, for example, skin-dominant, disease, since it is a limitation of this criteria project that the patient cohorts do not represent these subgroups. Similar limitations also pertain to several racial/ethnic groups (for example, African American/Black, Hispanic, and Asian patients) and to men with SLE, each only included in lower numbers (Table 3). It is important to independently test the EULAR/ACR criteria in these subgroups. Leukocyte counts, for example, are more frequently below 4,000/mm^3 in African Americans (33), which may have an influence on criteria performance. It is also possible that the academic center patient populations included differ from patients in community practice clinics. Investigators testing the new criteria in different populations are reminded about the critical importance of the correct attribution of each criterion. Criteria can only be counted when not better explained by another condition (see Supplementary Table 2, on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.40930/abstract). The attribution process requires diligence and clinical experience.

In summary, our multiphase methodologic approach and ensuing classification system using ANA as an entry criterion and weighted, hierarchically clustered criteria constitute a paradigm shift in the classification of SLE. These criteria have excellent performance characteristics and face validity, as the structure and weighting were designed to reflect current thinking about SLE. The inclusion of fever assists with the classification of early SLE. The separation of renal biopsy findings reflects their differential impact on the probability of SLE classification. These criteria have strong operating characteristics, with excellent sensitivity and specificity. This classification system was built using rigorous methodology that was both data-driven and expert-based. With the inclusion of over 200 SLE experts from multiple countries and medical disciplines, methodologists, patient advocates, and over 4,000 subjects, this work is the largest international, collaborative SLE classification effort to date.

ACKNOWLEDGMENTS

The authors wish to acknowledge the diligent work of Banita Aggarwal and Keshini Devakandan in data entry, data cleaning, queries to submitting investigators, data cutting, and maintenance of the derivation and validation cohorts; and of Corine Sinnette, MA in the preparatory work for the multicriteria decision analysis exercise.

Abstract

This year, the American College of Rheumatology (ACR) 1982 classification criteria for systemic lupus erythematosus (SLE) celebrate their 40th anniversary. From this start, the quest for optimal SLE criteria has led to the 1997 ACR update, the 2012 publication of the Systemic Lupus International Collaborating Clinics (SLICC) criteria, and, in 2019, the European League Against Rheumatism (EULAR)/ACR classification criteria. The latter have since been externally validated in more than two dozen studies and have become the gold standard inclusion criterion of SLE clinical trials. This comprehensive review attempts to follow the evolving success story of SLE classification, highlighting relevant decisions and their rationale, and discussing consequences for the way SLE is defined and managed.

Introduction

This year, 2022, sees the 40th anniversary of the publication of the 1982 American College of Rheumatology (ACR) classification criteria [1] and the 25th anniversary of their 1997 update [2], the 10th anniversary of the publication of the systemic lupus international collaborating clinics (SLICC) classification criteria [3] – and the 3rd anniversary of the publication of the European League Against Rheumatism (EULAR)/ACR classification criteria [4,5] for systemic lupus erythematosus (SLE). Accordingly, this is a

good timepoint to review SLE classification over the last forty years, which we consider an ongoing success story.

SLE is a challenging disease, both with regard to defining the entity in a clinically meaningful way, and with regard to devising classification criteria that are both specific and sensitive [6]. All of the four sets have been successful in the later, as shown in Table 1, which depicts the final sensitivities and specificities reported in the respective original publications – with the ACR 1997 update only validated later by the SLICC [3] and EULAR/ACR [4,5] efforts.

Beyond providing a necessary tool in defining a set of SLE patients for clinical trials, observational and translational studies on SLE, the criteria have also continuously shaped our picture of the disease. That said, it is important to reiterate that classification criteria are not what should decide on the individual diagnosis in a patient [7]. By necessity, they are designed to work on a group rather than on an individual level, and they need to simplify in order to remain practical tools. In consequence, there will be individual patients with SLE who do not fulfill the classification criteria, but still should be diagnosed with SLE, to receive proper treatment. Usually of lesser impact on the patient, there will also be patients fulfilling SLE classification criteria who suffer from conditions other than SLE. Accordingly, the diagnosis must remain with the properly trained physician [4,5], and treatment must not be limited to SLE patients fulfilling classification criteria.

Section snippets

Common ground

Before going into the development of the various sets of criteria, it appears sensible to explicitly look at the general rules that remained in place for all of them. The ACR 1982 criteria publication [1] defined “A person shall be said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.” In the SLICC criteria publication [3] this is worded “Criteria are cumulative and need not be present…

Criteria development over time

Since the early 1980s, there has been significant accrual of methodological knowledge on classification criteria development and how to avoid pitfalls that may lead to biased classification of patients [[8], [9], [10], [11], [12]]. Particularly, provisions were made to

avoid circular reasoning and self-fulfilling prophecies. In consequence, classification criteria projects have become ever bigger and more complex. This tendency can also be seen in the facts concerning the three major SLE…

The 1982 ACR criteria for SLE

Although there had been earlier efforts, the 1982 ACR criteria by Dr. Eng Tan and colleagues [1] arguably are the prototypical set of SLE classification criteria. The 4 in 11-item structure that resulted from these criteria could almost be said to have become so classical that the numbers were linked to the disease concept. For generations of physicians this set of criteria has shaped the picture of what is SLE.

The subcommittee analyzed the variables of the 1971 preliminary SLE criteria [13],…

The 1997 ACR criteria update

Shortly after the publication of the ACR criteria in 1982, anti-phospholipid antibodies were identified. The ACR criteria 1997 update [2] appropriately refers to Dr. Graham Hughes and Dr. Donato Alarcon-Segovia among others, citing a total of four pivotal publications [[14], [15], [16], [17]] and a paper by Piette and colleagues [18] suggesting reevaluation of the ACR criteria in this direction. At the same time, the LE cell test, which was available for less than half of the SLE patients…

The SLICC criteria

The SLICC group addressed a variety of concerns, which clinically included correlated terms relating to cutaneous lupus (such as malar rash and photosensitivity), the lack of inclusion of other cutaneous manifestations, the omission of neurologic manifestations, and the need for new standards in urinary protein quantification [3]. Immunologically, the omission of low complement levels, the need to include new information on anti-phospholipid antibodies, and above all the possibility to fulfill…

The EULAR/ACR criteria

From its beginning, the EULAR/ACR SLE classification project was based on ideas in three areas [6]. First, to maintain the specificity of the ACR criteria, while increasing sensitivity, and to enable early classification. Second, methodically, to follow a structure designed to maximize input, avoid circularity, and balance data and expert opinion. Third, contentwise, to test whether ANA could be repositioned as an entry criterion, based on its high sensitivity but low specificity, and to…

Information from the external validation of the EULAR/ACR criteria

Since the 2019 publication of the EULAR/ACR classification criteria, groups worldwide externally tested the new criteria. We performed a systematic literature review on PubMed with the string "(lupus OR SLE) AND criteria NOT review", which resulted in 4,409 citations. For the years 2019–2022, we extracted 92 abstracts. From 22 of these, the full publications contained information to at least derive an estimate for EULAR/ACR criteria sensitivity [40,[57], [58], [59], [60], [61], [62], [63], [64]…

Clinical trials

SLE clinical trials usually take several years, so that it is somewhat too early to expect published SLE clinical trials already using the EULAR/ACR 2019 criteria. With a search for recruiting phase 2 and phase 3 company trials on "lupus erythematosus, systemic" on clinicaltrials.gov↗, we found 39 trials listed as actively recruiting at the end of March 2022. For 26 of them, classification criteria were listed as inclusion criteria. In several of the remaining studies, patients were included by…

Lessons from criteria development on what SLE is

From the ACR 1982 criteria through the EULAR/ACR 2019 criteria it has held true that we do not have a unique laboratory parameter that defines who has SLE. ANA, which is at least sensitive enough to include almost all SLE patients, is clearly not specific enough to serve this purpose [37]. Antibodies to dsDNA, the next best guess, exclude around one quarter of patients with SLE [37], and when their sensitivity is forcefully increased, their specificity is prone to fall. While a meaningful…

Conclusions

The development of SLE classification criteria in the last forty years shows organic growth rather than radical breaks. Many of the clinical item concepts have remained in place over all this time. A few have entered the stage, such as SCLE and non-scarring alopecia with the SLICC criteria and fever with the EULAR/ACR criteria, and even fewer were given up over time. On approximately the same level, more immunological parameters were added, most prominently the complement components with the…

2022 Systemic lupus erythematosus remission in clinical practice. Message for Polish rheumatologists

Katarzyna Pawlak-Buś, Piotr Leszczyński

Department of Rheumatology and Rehabilitation of Rheumatology, Rehabilitation and Internal Medicine, Poznan University of Medical Sciences, Poland

Abstract

Systemic lupus erythematosus (SLE) is a complicated multiorgan disease and can lead to organ damage and increased risk of morbidity and mortality. The strategy of management while avoiding complications, especially caused by chronic glucocorticoid therapy, improves outcomes. Different definitions of the treatment goal in different configurations of lupus activity indexes have appeared over the years. In 2021 the definition of remission and recommendations for its achievement were published and it become a way to implement a treat-to-target strategy. The main goal of treatment has become DORIS (definition of remission in SLE) remission and the alternative LLDAS (low lupus disease activity state).

Prolonging remission with clinical and immunological lupus activity restrictions and minimizing or stopping steroid doses reduced flares and damage accrual. The analysis and neutralization of poor prognosis predictive factors in lupus could be the most beneficial for less morbidity and mortality and better quality of life.

Key words: systemic lupus erythematosus, Systemic Lupus Erythematosus Disease Activity Index, DORIS remission, lupus low disease activity state.

Introduction

Systemic lupus erythematosus (SLE) is a very heterogeneous and complex autoimmunological disease sometimes difficult to recognize and treat. Tremendous diagnostic progress, wider awareness of consequences of damage, and new therapy development have significantly reduced mortality and improved prognosis. The risk factors for organ damage progression and factors of poor prognosis force us to use the most effective possible treatment.

Our clinical experience gives us the basis for more aggressive therapy when we are dealing with a severe course of the disease, lupus nephritis, or symptoms of organ damage already at the beginning of the lupus diagnosis. Irreversible organs damage is a cause of permanent reduction in quality of life and disability of patients with SLE. We have evidence that one organ failure leads to another, regardless of disease activity control and treatment [1].

For more effective management, limited complications, and less progression of secondary organ damage we should identify the goal of the treatment. An easier and measurable target such as glycated hemoglobin A_{1c} (HBA_{1c}) and blood pressure in diabetes and hypertension respectively is more possible to adopt as a treatment goal. In lupus, this target is not simple and uncomplicated but regardless we must have a definition of the goal to achieve the best results to which we are striving.

Different definitions of remission in systemic lupus erythematosus

Due to heterogeneity in clinical and laboratory manifestations, SLE requires more complex measures of dis-

ease activity. The latest proposed definitions of remission used these composite algorithms based on lupus activity indices, patients' physical assessment, and glucocorticoid (GC) dosage.

Optimally expressed remission guarantees the patient reduced mortality, prolonged time to next flare or quiescence of the disease, and, most importantly, no organ damage. Complete remission should be our most preferred, but often the most restrictive treatment goal.

Previous longitudinal studies revealed a wide range of prevalence of different definitions of remission [2–4]. Authors reported that those who achieved remission had less lupus activity and a better prognosis over 5–10 years.

Despite a better understanding of lupus pathogenesis, immunology and clinical phenotypes of lupus patients there remain many unmet needs in developing innovative therapies that can potentially limit damage accrual.

However, for safer and more effective treatments to develop, to define treatment goals disease activity assessment tools are needed. In rheumatology in the field of rheumatoid arthritis or psoriatic arthritis, the treat-to-target strategy is used with positive effects, although it has not been proven in lupus.

An ideal therapeutic target is a remission defined and measured by validated tools for assessing disease activity. What does it mean in lupus? What is the most objective tool to consider and how to define remission in SLE? There remain difficult questions.

The discussion about the definition of remission in SLE has been going on for several years. Sustained state without signs and symptoms, quality of life level, fewer flares, lack of immunological activity – what is the definition of the treatment goal?

Different definitions of remission took into account lupus activity assessment indicators such as the SLEDAI score, physical global assessment (PGA), and kind of lupus treatment. These components were used in miscellaneous combinations with various cutoffs and therefore their comparison is impossible in terms of treatment effectiveness, especially innovative targeted therapies in clinical trials.

A cross-section survey of various combinations of definitions of remission was examined by Saccon et al. [5]. These data revealed the most common and the strongest goal in lupus from eight proposed and examined definitions according to the DORIS (definition of remission in SLE) framework [6].

Clinical SLEDAI (clinical Systemic Lupus Erythematosus Disease Activity Index 2000 – cSLEDAI) proved the most achievable goal in lupus in this extremely detailed study. Clinical SLEDAI is a variant of the lupus scale that does not take into account serology results and allows the use of antimalarials, low doses of GCs, and immunosuppressives (ISs) including biologicals.

Despite the lack of clinical activity of lupus, immune activity, i.e. increased antibody concentrations of anti-dsDNA, and decreased C3 and/or C4 complements, may indicate disease activity. Serologically active clinically quiescent disease, well described in the published literature, could be a sustained state without increased risk of flares and damage in summarized evidence [2, 7, 8].

Indeed, being aware of great developments in such fields as immunology and genetics, we are still looking for a biomarker of treatment efficacy, responder to targeted therapy, or predictors of poor outcomes [9]. Abnormal serology in SLE has been discussed by many researchers, and in most studies, immunological activity was not an independent predictor of damage, late morbidity, or mortality [10].

Another aspect of the construction of the final definition of remission was the influence of lupus therapy and its effect on disease activity, the safety of treatment, and the avoidance of dependent complications. Especially GCs and their advantages and disadvantages of chronic use are still discussed. Prednisone doses between 6 and 12 mg per day increase major organ damage by 50% [11].

Our knowledge is growing about increased mortality because of glucocorticoid-dependent damage, and our awareness is growing, which is visible in a significant decrease in mortality in the last decade. The evolution of treatment strategy has become a reality but its goal was not clearly defined.

The final recommendations from the International Task Force appeared in 2021 and constitute a summary of the discussions to date and consensus on a definition of remission in SLE (DORIS) [12]. The recommendations are a guide for clinicians, scientists, and researchers for better defining remission achievement and treat-to-target strategy implementation in patients with SLE.

The treat-to-target strategy improves outcomes in inflammatory diseases and strict targeting in lupus may improve patients' prognosis in the long term.

Treat-to-target strategy

The experience of the last decade of clinical practice has shown that the treat-to-target strategy led to improved care for patients with inflammatory rheumatic diseases.

The treatment strategy of any disease should be structured and targeted to achieve objectives that deliver long-term benefits. It is obvious that establishing a measurable, efficacious, validated treatment endpoint

for assessing remission in a multi-organ disease such as SLE is very complicated.

However, we know that the benefits for lupus patients outweigh any problems or difficulties in long-term perspectives. A goal-directed treatment approach has a profound impact on the management of chronic inflammatory diseases.

Rheumatologists learn from the experience of activity assessment in rheumatoid arthritis (RA). Lessens from RA give the proof that instruments using both clinical judgment and laboratory results indisputably improve outcomes by more effective standard treatment [13].

The fluctuating nature of SLE, relapsing-remitting disease with flares or persistently active disease, leads to irreversible organ damage such as stroke, heart infarction, end-stage renal failure, or glucocorticoid-dependent osteoporosis or cataract [14–16].

Moreover, the quality of life dramatically decreases due to our lack of vigilance and elimination of known risk factors. Both issues, high disease activity level due to poor control with damage progression, and chronic GC treatment with all the consequences, are responsible for the high mortality rate in SLE. Target definition in systemic lupus is expected to help reduce organ damage, improve long-term treatment outcomes and ultimately reduce mortality [17, 18].

The implementation of a treat-to-target strategy in lupus treatment is a very complicated process. It is determined not only by the limits of the remission definition items, but also by less measurable symptoms, pain, arthralgia, or fatigue.

Co-morbidities also affect the patient's condition or further impair the quality of life of lupus patients, such as depression secondary to disease or during neuropsychiatric manifestations. Management according to the treat-to-target strategy in lupus requires greater clinical knowledge and insight, efficiency, and determination in achieving the goal of disease remission.

Since 2012, international experts' work has been underway to define remission as part of the treat-to-target strategy in lupus. Our management and therapy in lupus depend on these essential activities which have become a basis of a treat-to-target strategy (Fig. 1).

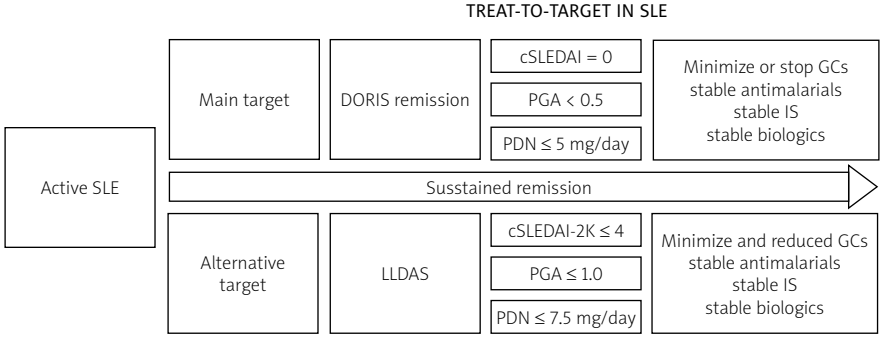
Numerous definitions have been explored in terms of duration and reduction in risk of damage, but currently the DORIS (definition of remission in SLE) remission and LLDAS (lupus low disease activity state) appear to be the most reliable and achievable goals [12, 19].

Definition of systemic lupus erythematosus remission, 2021

In 2016 an international task force published a framework for DORIS definition without final recommendations [6]. To meet the expectations in November 2021 the final recommendations were published and a simplified and universal definition was created that can be applied in clinical practice [12].

The International Task Force DORIS described remission as a complex of factors measured by cSLEDAI which does not take into consideration serology results, PGA to reflect the patient's perspective, and the dose of prednisone (PDN) as a factor affecting the risk of long-term organ damage.

Remission recommended by the DORIS task force is defined by cSLEDAI = 0, PGA < 0.5 points, and PDN ≤ 5 mg per day. The Systemic Lupus Erythematosus Disease Activity Index score is included in the global score system, which provides an overall measure of lupus activity alongside the European Consensus Lupus Activity Measurements SLAM (Systemic Lupus Activity Measure) [20] and, more complicated and difficult to



cSLEDAI – clinical Systemic Lupus Erytematosus Disease Activity Index, GCs – glucocorticosteroids, IS – immunosuppressives, LLDAS – lupus low disease activity state, PGA – Physical Global Assessment, PDN – prednisone.

Fig. 1. Remission treat-to-target strategy in systemic lupus erythematosus.

apply, the individual organ assessment British Isles Lupus Assessment Group Index (BILAG) [21].

Evaluation of lupus activity by SLEDAI score requires the application of certain principles, but most of the points of assessment are not objective and depend on clinical judgment. It follows that we do not have independent tools for lupus assessment activity. Similar doubts apply to PGA, which reflects the health-related quality of life from patients' perspectives.

Nevertheless, remission by any definition is associated with improving quality of life, which is the most important factor for patients with SLE. The principle of lupus treatment for rheumatologists who deal with guiding the patient should be minimizing GCs doses, and this is our direct goal in the definition not only of DORIS remission. Maintaining standard treatment during remission by ISs and/or biologics is necessary and antimalarials are allowed.

The most restrictive definition and most expected clinical condition is DORIS complete remission with no clinical and serological activity (SLEDAI = 0) with PGA below 0.5 points and with maintenance antimalarial therapy without the need for any dosage of GCs and IS or biologics.

The frequency of SLE remission in available data and clinical practice is not high and is still insufficient. In the literature, many propositions of alternative, more achievable goals have been presented.

Remission key messages are shown in Table I.

Table I. Remission key messages

Remission is an achievable and desirable target in SLE and a part of the treat-to-target strategy which can be applied in clinical practice
Optimally expressed remission guaranteeing the patient reduced mortality, prolonged time to next flare and the most important no organ damage
Chronic GCs therapy is a major independent predictor organ damage accrual. The principle of lupus treatment for rheumatologists should be minimizing or consider withdrawing GCs treatment
The final recommendations 2021 constitute a summary and consensus on a definition of remission in SLE – DORIS remission
Lupus low disease activity state is alternative target which is a compromise between achievable therapeutic effects and minimizing GCs doses

Low systemic lupus erythematosus activity

Multiple studies based on multiethnic and multicenter cohorts evaluated lupus activity according to alternative targets before the DORIS recommendations for remission were published. We have several definitions of low disease activity widely described in the literature.

The term low disease activity (LDA) was defined by Toronto Lupus Cohort investigators and included cSLEDAI ≤ 2 points (without serology results index) and in the most restrictive treatment rules GCs and IS exclusion [22].

The remission objective proposed by Franklyn et al. [23], low lupus disease activity state (LLDAS), is a potential alternative target in our lupus treatment strategy. Among the components of the definition of LLDAS are SLEDAI-2K ≤ 4 points and PGA ≤ 1.0 points, and a minimal dose of PDN ≤ 7.5 mg per day. In remission by LLDAS definition, an additional criterion of any clinical or serological activity must be met.

Due to the level of listed indicators reflecting disease activity, this definition represents a compromise between achievable therapeutic effects and minimizing GC doses. The strongest evidence refers to time-dependent reducing disease flares and organ damage accrual in patients with remission determined by LLDAS definition [23, 24]. Consequently reduced damage progression is associated with decreased mortality by almost 70% as well as improving patient outcomes [25].

Furthermore, based on post-hoc analysis of innovative therapies in SLE, belimumab or anifrolumab, we know that LLDAS has a potential validated outcome measure in clinical trials [26, 27].

Prevalence, predictors and prognostic benefits of remission

Prevalence of remission depends on management and utilized available treatment options and is still an unmet need in the population of lupus patients. In the therapy of systemic lupus, we are aware of the limited effectiveness of possible treatments and problems with prevention flares, persistently active disease, and damage accrual.

Previous studies have revealed that especially the initial years of the disease have implications for the propensity for flare or remission and they are predictive of long-term outcomes. More aggressive treatment for induction, consolidation, and maintenance of the remission state seems to be a good strategy but not so common and not always feasible. In the future perspectives, remission is a state we should strive for because of fewer complications, lower mortality, and better long-term outcomes.

The percentage of remission in different studies varies between 63 and 74.8% of LLDAS according to Tani et al. [28], and 44% in Asian-Pacific countries according to Golder et al. [24]. Different potential definitions and

their impact on capturing the remission state and predicting damage by the SLICC/ACR Damage Index were described by Saccon et al. [5].

As mentioned in the introduction, in this Italian multicenter study, a 69.2% remission rate according to the DORIS definition was noted. Various definitions examined in this study were based on single or a combination of remission items such as SLEDAI score, PGA, and PDN doses [6, 12].

The most attainable definition to meet was cSLEDAI, which in BLISS trials, provided with antibodies against B-lymphocyte stimulator (BLyS) in SLE, was shown to be a target and clinical positive endpoint of belimumab treatment. Clinical SLEDAI is only one component of remission assessment by both LLDAS and DORIS definitions. Low lupus disease activity state is easier to achieve than DORIS remission, and it is related to PDN doses but also patients' self-assessment by PGA.

Discussion about remission with and without treatment, especially GCs, is a very important point of consideration by experts. Complete cure of the disease is an obvious target for management and treatment in any disease, but in SLE, as a chronic disease, it is not reachable.

Although some predictors of damage are non-reversible, such as non-Caucasian ethnicity and older age, high lupus activity level and chronic GCs therapy directly associated with damage are possible to treat and reduce significantly. Moreover, with so much progress in the diagnostics and treatment of SLE, predictive factors help us to adjust the level of the treatment to achieve the best long-term results.

Definitions of remission in SLE and LLDAS remission have been compared in the field of reducing flares and damage progression in various studies [29, 30]. Based on these data, attempts were made to reach a definite conclusion that deeper and longer remission is associated with stronger protective effects against organ damage and its consequences. The remission achieved by maintenance therapy in different published data is in the range of 25–37% [17, 31, 32].

Evidence from observational studies shows that in the populations of South and North America, Asia, and especially Europe, prolonged DORIS remission on treatment was associated with reduced damage accrual [3, 31, 33, 34].

A complete remission requiring no therapy is very rare in both research and clinical practice, and even more unique given the length of remission. In a Canadian study patients with 5 consecutive years of complete remission not requiring medication accounted for 1.7% of the whole cohort [35] and in other analyses did not exceed 7% [3, 4].

Nevertheless, prolonged drug-free remission is very rare and difficult to achieve in studies but also in clinical practice. First of all, the most important goal reduction of damage accrual and increasing time to flare depends on remission duration and its level [5, 4].

Duration of remission was a key point to consider in published data, because of its association with reduced organ damage. In numerous studies published by Zen et al. [3, 36] Caucasian SLE patients were protected against damage after at least two consecutive years in remission but better outcomes in damage accrual were achieved after prolonged maintained remission defined over 5 years.

However, data from the largest US population DORIS and LLDAS remission studies published by Petri et al. [17] have shown that reducing the risk of long-term damage is possible even with a lower percentage of time in LLDAS on treatment.

The difficulties with remission achievement in such a complicated, heterogeneous disease mean that any period of low SLE activity, especially remission, is an achievement with measurable long-term benefits [5, 22].

A review of 41 SLE studies with over 17 thousand patients revealed the percentage of achieving at least one year of maintained remission as 42.4% to 88% and remission predictors associated with lower accrual of organ damage and better quality of life among lupus patients. In this systemic review, the predictive factors older age at diagnosis, lower baseline SLE activity, and absence of major organ involvement were identified; however, positive serology results were negatively associated with remission [37].

Especially prolonged remission is an achievable and desirable target, and we have multiple proofs that are associated with benefits. Consequently, the path to achieving these benefits should be determined by the principles of treatment.

Chronic GC therapy followed by evidence is a major independent predictor of organ damage accrual in addition to typical steroid-dependent complications such as diabetes, osteoporosis, avascular necrosis, or cataract [15, 38].

Nowadays, with so much knowledge on complications of GCs therapy available, restriction of GCs use seems to be the overriding principle. Unfortunately, tapering and withdrawal of GCs before immunosuppressive therapy to protect against flare and organ damage according to recommendations is not a routine good clinical practice everywhere [16, 39, 40].

Achieving long-term remission and the decision to discontinue GCs therapy do not result in an increased risk of flare, interestingly even in lupus nephritis, where decisions to withdraw GCs and ISs could be more predisposing to an exacerbation [41, 42].

A low level of SLE activity according to DORIS remission or LLDAS is the ideal situation to consider tapering or withdrawing treatment after assessment of the time of recent disease flare and risk factors. The physician's decision depends on clinical judgment and a good patient's condition; nevertheless, it may not be disturbed by clinically irrelevant symptoms such as arthralgia, pain, or fatigue. Most of the SLE patients after treatment-induced sustained remission discontinued GCs successfully while only a minority of patients had non-significant manifestations.

Tani et al. [42] presented the frequency range of 2.4–50% of GCs-free SLE patients in the cohorts reported in the literature. In this study, of patients who achieved remission and had GCs treatment discontinued, flares occurred in 23% of SLE patients at 2 years; by comparison, in the group of patients who required GCs maintenance therapy, most of the patients (69.8%) had at least one flare during 6 years of follow-up. These data revealed the point of going into GCs-free remission even if this goal required effort to achieve it.

Immunosuppressive therapy was a basic treatment in the context of induction and consolidation of remission. According to recommendations, IS discontinuation should be the next step after GCs tapering or withdrawal following disease activity control. Flares after stopping prolonged ISs are not uncommon although antimalarial treatment can reduce the risk and bring benefits.

Hydroxychloroquine (HCQ) is a cornerstone of SLE therapy and a very important factor especially in a discussion about remission. Consistent antimalarial treatment reduced the risk of flares [43] and, more importantly, mortality [44, 45], and during remission is a beneficial and desirable treatment. The definitions of remission allow the use of chloroquine (CQ) or HCQ for disease activity control.

Despite still limited treatment options in SLE, remission regardless of definition is an achievable goal and reducing the risk of damage and progressive destructive disease depends on our awareness of GCs prolonged overtreatment, sustained HCQ, and reasonable immunosuppressive therapy. The best objective decisions for the SLE patient are made in the longterm perspective, taking into account the risks and benefits of the treatment and management including prognostic predictive factors.

Conclusions

The treat-to-target strategy in rheumatology improved outcomes and should be a key to success in the management of SLE patients. The construction of the definition proper of the treatment goal was an achievement in SLE and has the potential for limitation of organ damage accrual.

Reduction of flares and damage accrual is possible with sustained prolonged remission. Remission components, in any definitions of DORIS or LLDAS, revealed reduced overall activity levels, low SLE activity in cSLEDAI assessed by a physician, good condition in PGA score assessed by patients, and a low dose of GCs with basic antimalarial therapy, ISs, and/or biologics.

Successful implementation of DORIS remission and LLDAS definition as a treatment goal allow the adoption of a treat-to-target strategy for greater damage protection in clinical practice. Chronic GCs treatment is the most dangerous predictor of poor prognosis, an independent risk factor of organ damage in the course of SLE.

The aggressive effective treatment of SLE flares by a high dose of GCs and strong ISs in induction therapy, consolidation of clinical improvement, and achieving prolonged, sustained remission is a way for withdrawing GCs and avoiding complications. The deeper and longer the remission is, the stronger is the protective effect, with less morbidity and mortality, and better long-term outcomes.

The authors declare no conflict of interest.

Guidelines

BRITISH SOCIETY FOR RHEUMATOLOGY

The British Society for Rheumatology guideline for the management of systemic lupus erythematosus in adults

Caroline Gordon[1,2,3], Maame-Boatemaa Amissah-Arthur[1], Mary Gayed[1,3], Sue Brown[4], Ian N. Bruce[5,6], David D'Cruz[7], Benjamin Empson[8], Bridget Griffiths[9], David Jayne[10,11], Munther Khamashta[12,13], Liz Lightstone[14], Peter Norton[15], Yvonne Norton[15], Karen Schreiber[13] and David Isenberg[16] for the British Society for Rheumatology Standards, Audit and Guidelines Working Group

Key words: lupus, diagnosis, assessment, monitoring, management, immunosuppressants, treatment, efficacy, non-biologics, biologics.

Scope and purpose of the guideline

Background

SLE (or lupus for short) is a multisystem, autoimmune disease, involving complex pathogenetic mechanisms that can present at any age. It most commonly presents in women in the reproductive age group, although lupus is increasingly recognized after the age of 40 years, particularly in Europeans [1–3]. Lupus affected nearly 1 in 1000 of the population in the UK in 2012 [4] and was

NICE accredited
www.nice.org.uk/accreditation

NICE has accredited the process used by the BSR to produce its guidance on the management of systemic lupus erythematosus in adults. Accreditation is valid for 5 years from 10 June 2013. More information on accreditation can be viewed at www.nice.org.uk/accreditation. For full details on our accreditation visit: www.nice.org.uk/accreditation.

most frequently observed in people of African-Caribbean and South Asian descent [4–6]. The age-standardized incidence in the UK according to the Clinical Practice Research Datalink is 8.3/100 000/year for females and 1.4/100 000/year for males [4], and the highest incidence rates are seen in those of African-Caribbean descent: 31.4/100 000/year, compared with 6.7/100 000/year for those of white European descent. The mean age at diagnosis is 48.9 years [4], but it is lower in those of African ancestry in the UK [4–6] and North America [2, 7].

The disease is prone to relapses and remissions, resulting in considerable morbidity due to flares of disease activity and accumulated damage, and an increased risk of premature death, mostly due to infection or cardiovascular disease [2, 8–14]. Death from active lupus is rare in the UK [15, 16]; however, a 10% mortality over 20 years and a mean age of death of 53.7 years was recently reported [16]. About one-third of SLE patients in the UK develop LN [16–18]. Patients of African ancestry tend to present young with LN in the UK, as in the USA and elsewhere [2, 17, 19], and are at considerable risk of developing end-stage renal disease (ESRD) and of dying prematurely. In another UK cohort, ESRD occurred in 20% of LN patients within 10 years of diagnosis, and the mean age at death in LN patients was 40.3 years, with an average of 7.5 years between development of LN and death [18].

The mainstay of therapy for active lupus until recently has been NSAIDs, CSs, antimalarials such as HCQ, and immunosuppressants such as AZA and CYC, although only prednisolone and HCQ are licensed for lupus [8, 20]. With the exception of LN, there were relatively few trials until the last 15 years, and in 2011, belimumab became the first drug to be licensed for the treatment of active lupus for over 50 years [20]. New therapies that will reduce the need for CSs to control lupus activity and to reduce the development of damage and infection are needed to improve outcome [10–12, 16, 21]. In the meantime it is important to manage patients optimally with the treatment strategies that are available.

Need for the guideline

Despite some improvement in survival data over the last 40 years [2, 13], lupus patients still die on average 25 years earlier than the mean for women and men in the UK [16]. The disease can present with slowly or rapidly progressive active disease at any age and can be associated with the rapid accumulation of damage if not promptly diagnosed, appropriately treated and regularly monitored [2, 8, 14, 19, 20]. An up-to-date comprehensive guideline to optimize these aspects of management that is consistent with current evidence and National Health Service (NHS) practice is warranted to improve the outcome of this variable and potentially life-threatening disease that

Table 1 Levels of evidence and grades of recommendation for diagnosis, assessment and monitoring of non-renal SLE

Statement/item	Number of studies	Overall SIGN level of evidence	Grade of recommendation	Selected references covering items discussed in text
Diagnosis from clinical and serological features				
Prognostic value of:				
Clinical features	29	2++	B	[7, 10, 26–35]
ANA	8	2++	B	[26–29, 34, 36–38]
Anti-dsDNA antibodies	17	2++	B	[26–29, 37, 39, 40]
Low C3/C4 levels	13	2+	C	[27, 41–46]
Anti-Ro/La antibodies	4	2+	C	[10, 27–29, 37]
aPLs	12	2++	B	[26, 27, 29, 47]
Assessment and monitoring of SLE disease activity and damage				
Clinical flare	6	2+	C	[48, 49]
Good diagnostic utility of:				
clinical and laboratory monitoring	28	2++	B	[11, 16, 21, 32, 50–57]
anti-dsDNA and C3/C4 levels	14	2++	B	[40, 43, 44, 46, 49, 58–60, 61–63]
aPL repeat	–	–	D	[47]
anti-Ro/La for neonatal lupus	6	1+	A	[64, 65]
CRP low or normal unless infection	4	2++	B	[66–69]
ESR correlates with active lupus	2	2+	C	[69, 70]
Prognostic value of lupus disease activity and damage indices	>60	2++	B	Reviewed in [12, 71] [11, 14–16, 32, 72, 73]
Monitoring and treating cardiovascular risk factors in SLE patients	6	2+	C	Reviewed in [22, 71, 74–76]
Frequency of monitoring SLE:				
For active disease, every 1–3 months after diagnosis or flare	2	2+	C	[72, 77]
Low/no disease activity, stable treatment: 6- to 12-monthly	–	–	D	Expert opinion
Monitoring for drug toxicity/levels	2	2+	C	[78, 79]

Table 2 Levels of evidence and grades of recommendation for medications used in the treatment of non-renal SLE

Treatment (recommended target dosage)	Main uses (unless contra-indications)	Total number of papers	Overall SIGN level of evidence	Grade of recommendation	Comments: including number of reports and references for RCTs, cohort studies and systematic reviews/meta-analyses (SRs)
Antimalarials: HCQ $\leqslant$6.5 mg/kg/day	Mild lupus, prevent flare in all patients, prevent damage, steroid-sparing	45	1 ++	A	7 RCTs [80–86]; 36 cohort studies [87–120]; 2 SRs [121, 122]
MTX $\leqslant$25 mg/week	Mild and moderate lupus, prevent flare, steroid sparing	12	1+	A	2 blind, 1 open-label RCTs [123–125]; 5 cohort studies [126–130]; 2 case series [131, 132]; 2 SRs [133, 319]
NSAIDs	Symptom control in mild non-renal lupus only	1	3	D	1 SR covers case series/reports [134]
Sunscreen (high-SPF UV-A and UV-B)	Prevents UV-induced rashes and other manifestations	7	2 ++	B	1 blind RCT [135]; 5 cohort studies [136–140]; 1 case series [141]
Low-dose oral prednisolone ($\leqslant$7.5 mg)	Mild lupus and to prevent flares	0	4	D	Expert opinion
Higher doses of oral prednisolone $\leqslant$0.5 mg/kg/day	Moderate lupus and prevention of flares	0 2	4 2+	D C	To prevent flare: 1 blind RCT [46] and 1 open-label RCT [60]
I.m. triamcinolone	Moderate lupus	1	2+	C	1 open-label RCT [142]
I.m. methylprednisolone (80–120 mg)	Moderate lupus	0	4	D	Expert opinion
I.v. methylprednisolone (100–250 mg)	Moderate lupus	1	2+	C/D	1 blind RCT for 100 mg *vs* 1000 mg [143]
I.v. methylprednisolone (500 mg–1 g) $\times$ 1–3 pulses	Moderate and severe lupus	6	2+	C	2 small blind RCTs [143, 144]; 1 open-label trial [145]; 3 cohort studies [146–148]
AZA (if TPMT normal) 2–3 mg/kg/day	Moderate lupus, prevent flare, steroid sparing	10	2+	C	4 open-label RCTs [149–152]; 5 cohort studies [153–157]; 1 case series [158]
MMF 2–3 g/day	Moderate/severe lupus, prevent flare, steroid-sparing	13	2 ++	B	3 open-label RCTs [159–161]; 7 cohort studies [162–168]; 1 case series [169]; 2 SRs [133, 170]
Mycophenolic acid/sodium 1.44–2.16 g/day	For patients intolerant of MMF	2	3	D	1 open-label RCT [171]; 1 cohort study [172]

(continued)

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

Table 2 Continued

Treatment (recommended target dosage)	Main uses (unless contra-indications)	Total number of papers	Overall SIGN level of evidence	Grade of recommendation	Comments: including number of reports and references for RCTs, cohort studies and systematic reviews/meta-analyses (SRs)
Ciclosporin $\leqslant$2.5 mg/kg/day	Moderate/severe lupus including cytopenias, prevent flare, steroid-sparing	11	2+	C	2 open-label RCTs [152, 173]; 8 cohort studies [174–181]; 1 SR [133]
Tacrolimus 1–3 mg/day (assess drug levels)	Moderate/severe lupus, steroid-sparing	3	3	D	2 cohort studies [182, 183]; 1 SR [133]
LEF (20 mg/day)	Moderate lupus without subacute rash	3	3	D	1 small blind RCT [184]; 1 cohort study [185]; 1 SR [133]
CYC (see text for dosing)	Severe lupus, including NPSLE, prevent flare, steroid-sparing	30	2 ++	B	4 open-label RCTs [186–189]; 25 cohort studies covered by 1 SR [133]
Rituximab 1000 mg $\times$ 2	Refractory severe and moderate lupus; steroid-sparing	33	2+	C	1 blind RCT [190, 191]; 3 open-label RCTs [192–194]; 24 cohort studies [195–198 not in SRs]; 2 case series [194, 199]; 2 SRs, including 1 meta-analysis [200, 201]; 1 SR with 26 extra case reports/series [202]
Belimumab 10 mg/kg/4 weeks	Refractory moderate/severe lupus; prevent flare and steroid-sparing (not NPSLE)	5	1+	B	2 phase III blind RCTs [203, 204]; 1 phase II blind RCT [205]; *post hoc* combined analysis [206]; 1 open-label extension [207, 208]; 1 meta-analysis [209]
IVIG (see text)	Refractory severe lupus (including catastrophic APS)	19	2–	D	Rarely indicated: 3 open-label trials [210–212]; 10 cohort studies [213–222]; 4 case series [223–226]; 2 SRs with 1 meta-analysis [227, 228]
Plasmapharesis	TTP; refractory severe SLE	10	2 ++ for TTP; 3 otherwise	B for TTP; D otherwise	Rarely indicated: 9 cohort/case series [229–237]; 1SR [238]

TPMT: thiopurine S-methyltransferase (see text); TTP: thrombocytopaenic purpura.

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

causes considerable morbidity. There have been no previous UK-based guidelines for lupus. The European (EULAR) recommendations for the management of lupus in general were not very detailed and were published in 2008 [22], although more specific recommendations were published for neuropsychiatric lupus in 2010 [23], and joint EULAR and European Renal Association–European Dialysis and Transplant Association (EULAR/ERA-EDTA) recommendations for LN were published in 2012 [24], as well as ACR guidelines for the management of LN in 2012 [25].

Objectives of the guideline

The aim of this guideline was to produce recommendations for the management of adult lupus patients in the UK that cover the diagnosis, assessment and monitoring of lupus and the treatment of mild, moderate and severe active lupus disease, but which do not imply a legal obligation. The resulting recommendations are based on an extensive review of the literature up to June 2015 to produce evidence-based guidelines, particularly for the treatment of non-renal lupus, supplemented as necessary by expert opinion and consensus agreement (Tables 1 and 2). The guideline development group recommended that patients with LN are managed according to the EULAR/ERA-EDTA recommendations for LN [24] and provide their strengths of agreement (SOAs) with a summary of the most important items in those recommendations (Table 3).

Target population, target audience and stakeholder involvement

The guidelines address the management of adult patients only and have been developed by a multidisciplinary guideline development group set up by the British Society for Rheumatology (BSR) and led by C.G., consisting of academic (C.G., I.N.B., D.D.C., M.K., D.I.) and NHS consultants in rheumatology (M.A., B.G.) and nephrology (D.J., L.L.), rheumatology trainees (M.G., K.S.), a GP (B.E.), a clinical nurse specialist (S.B.), a patient representative (Y.N.) and a lay member (P.N.). All participants declared any conflicts of interest and these are listed at the end of this article. The target audience includes rheumatologists and other clinicians such as nephrologists, immunologists and dermatologists, trainees in these specialties and emergency medicine, GPs, clinical nurse specialists and other allied health professionals involved in the care of adult lupus patients. Opinions of other key stakeholders such as other consultant members of the BSR, additional trainees, podiatrists, nurse specialists and representatives of Lupus UK were sought during the preparation of these guidelines.

Areas that the guideline does not cover

This guideline does not cover the evidence for topical or systemic therapy for isolated cutaneous lupus, nor does it discuss paediatric lupus, as there is relatively little literature on paediatric lupus. As the disease tends to come on after puberty, most of the recommendations are likely to be appropriate for children/adolescents, with suitable dose modifications. We provide only summary advice about the use of drugs in the management of pregnant lupus patients, and refer to the extensive review of drugs used in pregnancy and breast-feeding that have been recently published [239, 240]. The management of complications of lupus, including chronic fatigue, cardiovascular risk, osteoporosis, infection and cancer risk are not discussed in detail, as these issues should be managed as for other patients with similar risk factors according to national and international guidelines. Management of thrombosis will depend on whether or not the criteria for APS are met [241].

Rigor of development

Selection of questions for the literature review, and statement of extent of previous National Institute for Health and Care Excellence, Royal College of Physicians, and Scottish Intercollegiate Guidelines Network guidelines

A multidisciplinary guideline development group was formed and followed the BSR Protocol for Guidelines and EULAR standardized operating procedures to define the focus of the work, the target population and the target audience. Discussions were supplemented by consensus-building strategies, including a modified Delphi technique, in order to reduce and clearly define the list of research questions to be addressed by the literature search (see supplementary data section Search strategy, available at *Rheumatology* Online). There are no BSR, Royal College of Physicians (RCP), National Institute for Health and Care Excellence (NICE) or Scottish Intercollegiate Guidelines Network (SIGN) guidelines or recommendations for the management of lupus in the UK to help improve the outcome of this variable and potentially life-threatening disease, but lupus has been included in the on-line resource Map of Medicine.

Literature review: eligibility criteria and limitations of the search

A systematic search of MEDLINE (PubMed) and the Cochrane Database of Systematic Reviews was performed, and all publications in peer-reviewed English language journals up to June 2015 were considered. A detailed search was performed using an array of relevant terms (see supplementary data section Search strategy and supplementary Table S1, available at *Rheumatology* Online), and papers were screened for eligibility based on their title, abstract and/or full content. Studies were eligible if they had studied at least 50 patients for prevalence and prognosis of manifestations, 10 patients for diagnosis and monitoring, or 5 patients for therapy.

Studies on animals, children, review articles, commentaries, conference abstracts or statements, and expert opinion statements were excluded. Narrative review articles and existing guidelines were checked for references, but only meta-analyses and systematic reviews were included, together with original research articles, in the analysis. Over 8000 articles were identified during the literature search, and over 600 were deemed eligible for

Table 3 Strength of agreement of authors with the main EULAR/ERA-EDTA recommendations for the management of LN

Management of SLE patients with renal involvement	SOA[a]
Assessment of renal involvement	
1. Indications for first renal biopsy in SLE	97
Any sign of renal involvement—in particular, urinary findings such as reproducible proteinuria $\geqslant$0.5 g/24 h, especially with glomerular haematuria and/or cellular casts—should be an indication for renal biopsy. Renal biopsy is indispensable since, in most cases, clinical, serologic and laboratory tests cannot accurately predict renal biopsy findings.	
2. Pathological assessment of kidney biopsy	98
The use of the International Society of Nephrology/Renal Pathology Society (ISN/RPS) 2003 classification system is recommended, with assessment not only of active and chronic glomerular and tubulointerstitial changes, but also of vascular lesions associated with aPLs/APS.	
Treatment of renal involvement	
3. Indications and goals of immunosuppressive treatment in LN	98
3.1 Initiation of immunosuppressive treatment should be guided by a diagnostic renal biopsy. Immunosuppressive agents are recommended in class III_A or $III_{A/C}$ ($\pm$V) and IV_A or $IV_{A/C}$ ($\pm$V) nephritis, and also in pure class V nephritis if proteinuria exceeds 1 g/24 h despite the optimal use of renin–angiotensin–aldosterone system blockers.	
3.2 The ultimate goals of treatment in LN are long-term preservation of renal function, prevention of disease flares, avoidance of treatment-related harms and improved quality of life and survival. Treatment should aim for complete renal response with UPCR <50 mg/mol and normal or near-normal (within 10% of normal GFR if previously abnormal) renal function. Partial renal response, defined as $\geqslant$ 50% reduction in proteinuria to subnephrotic levels and normal or near-normal renal function, should be achieved preferably by 6 months but no later than 12 months following initiation of treatment.	98
4. **Treatment of adult LN—initial treatment**	
4.1 For patients with class III_A or $III_{A/C}$ ($\pm$V) and class IV_A or $IV_{A/C}$ ($\pm$V) LN, mycophenolic acid (MPA) (MMF target dose: 3 g/day for 6 months, or MPA sodium at equivalent dose) or low-dose i.v. CYC (total dose 3 g over 3 months), in combination with glucocorticoids, are recommended as initial treatment as they have the best efficacy/toxicity ratio.	93
4.2 In patients with adverse prognostic factors (acute deterioration in renal function, substantial cellular crescents and/or fibrinoid necrosis), similar regimens may be used, but CYC can also be prescribed monthly at higher doses (0.75–1 g/m^2) for 6 months or orally (2–2.5 mg/kg/day) for 3 months.	92
4.3 To increase efficacy and reduce cumulative glucocorticoid doses, treatment regimens should be combined initially with three consecutive pulses of i.v. methylprednisolone 500–750 mg, followed by oral prednisone 0.5 mg/kg/day for 4 weeks, reducing to $\leqslant$ 10 mg/day by 4–6 months	98
4.4 In pure class V nephritis with nephrotic-range proteinuria, MPA (MMF target dose 3 g/day for 6 months) in combination with oral prednisone (0.5 mg/kg/day) may be used as initial treatment based on better efficacy/toxicity ratio. CYC or calcineurin inhibitors (ciclosporin, tacrolimus) or rituximab are recommended as alternative options or for non-responders.	95
4.5 AZA (2 mg/kg/day) may be considered as an alternative to MPA or CYC in selected patients without adverse prognostic factors (as defined 4.2), or when these drugs are contraindicated, not tolerated or unavailable. AZA use is associated with a higher flare risk.	96
Subsequent treatment	
4.6 In patients improving after initial treatment, subsequent immunosuppression is recommended with either MPA at lower doses (initial target MMF dose 2 g/day) or AZA (2 mg/kg/day) for at least 3 years, in combination with low-dose prednisone (5–7.5 mg/day). Gradual drug withdrawal, glucocorticoids first, can then be attempted.	97
4.7 Patients who responded to initial treatment with MPA should remain on MPA unless pregnancy is contemplated, in which case they should switch to AZA at least 3 months prior to conception.	98
4.8 Calcineurin inhibitors can be considered in pure class V nephritis.	93
Refractory disease	
4.9 For patients who fail treatment with MPA or CYC, either because of lack of effect (as defined above) or due to adverse events, we recommend that the treatment is switched from MPA to CYC, or CYC to MPA, or that rituximab be given.	95
5. **Adjunct treatment in patients with LN**	
5.1 Angiotensin-converting enzyme inhibitors or angiotensin receptor blockers are indicated for patients with proteinuria (UPCR >50 mg/mmol) or hypertension.	98
6. **Management of end-stage renal disease in LN**	
6.1 All methods of renal replacement treatment can be used in lupus patients, but there may be increased risk of infections in peritoneal dialysis patients still on immunosuppressive agents, and vascular access thrombosis in patients with aPLs.	98
6.2 Transplantation should be performed when lupus activity has been absent, or at a low level, for at least 3–6 months, with superior results obtained with living donor and pre-emptive transplantation. aPLs should be sought during transplant preparation because they are associated with an increased risk of vascular events in the transplanted kidney.	96
7. **APS-associated nephropathy in SLE**	
7.1 In patients with lupus and APS-associated nephropathy (APSN), HCQ and/or antiplatelet/anticoagulant treatment should be considered.	91

detailed review by at least two members of the group. There was considerable overlap in the topics covered by the papers, which were reviewed by various members of the group.

Development of the guideline: levels of evidence and consensus agreement

The recommendations were developed in line with the BSR's Guidelines Protocol, using RCP, SIGN and AGREE II methodology to assess the level of evidence (LOE) and grade of recommendation (GOR). Papers selected for review and the evidence obtained from them were categorized by at least two members of the group, according to the study design, using the SIGN methodology (supplementary Table S2, available at *Rheumatology* Online), and the level of the evidence was graded by combining information on the design and validity of the available research studies to provide the GOR for each component of each statement. The results of the literature search were summarized, aggregated and distributed to the expert committee by three of us (C.G., M.G., M.A.), and the GOR for each item was ratified by the expert committee. Draft recommendations were discussed and rephrased at a face-to-face meeting and subsequently by email, following an updated literature review. The LOEs and the GORs for the data supporting the guideline recommendations are shown in Tables 1 and 2. Finally, the six recommendations for the management of SLE and the main items in the EULAR/ERA-EDTA recommendations for LN [24] (Table 3) were voted on by clinical members of the guideline development group. For each recommendation, the SOA of all clinical members of the group was sought on a scale of 1 (no agreement) to 10 (complete agreement); the mean percentage agreement was calculated and is shown after each recommendation (all >90% and supported by other members of the group). The guideline will be reviewed in 5 years' time.

The guideline

Eligibility criteria

This guideline is designed to cover the management of adult patients with SLE by healthcare professionals. These recommendations are based on the literature review covering the diagnosis, assessment, monitoring and treatment of mild, moderate and severe lupus, including neuropsychiatric (NP) disease. The focus of the literature review was on non-renal disease, as the EULAR/ERA-EDTA recommendations for LN (see below) were published [24] close to the time that we started work on this guideline.

Exclusion criteria

Management of paediatric lupus, renal lupus, topical treatment for cutaneous lupus, and drug treatment in pregnancy have been excluded from our literature search and guideline development. BSR guidelines on the use of drugs in pregnant patients with rheumatic diseases (including lupus) have been developed in parallel with this guideline.

Introduction to the recommendations and supporting evidence

For each question addressed by the literature review (supplementary data section Search strategy, available at *Rheumatology* Online), we provide first the recommendations and the overall LOE, GOR and SOA for each, followed by the rationale. The rationale consists of a summary of the evidence supporting the statements (including cautions in the case of drug therapy). It is organized by topic and includes some key points about the studies leading to the recommendations and a conclusion for each topic discussed. The number of studies and types of studies (with references) leading to the LOE and GOR are summarized in Table 1 for the items contributing to the recommendations on diagnosis, assessment and monitoring of lupus, and in Table 2 for those relating to the treatment and prevention of mild, moderate and severe non-renal lupus. In Table 3 we provide our SOA with key points of the EULAR/ERA-EDTA recommendations for the management of LN [24], so that the management of the most important aspects of lupus are covered by this guideline in a single document.

Recommendations for clinical and serological features prompting consideration of a diagnosis of SLE

(i) SLE is a multisystem autoimmune disorder. The diagnosis requires a combination of clinical features and the presence of at least one relevant immunological abnormality. If there is a clinical suspicion of lupus, blood tests (including serological marker tests) should be checked (LOE 2++, GOR B, SOA 98%).

(ii) ANAs are present in ~95% of SLE patients. If the test is negative, there is a low clinical probability of the patient having SLE. A positive ANA test occurs in ~5% of the adult population, and alone it has poor diagnostic value in the absence of clinical features of autoimmune rheumatic disease (2++/B, SOA 96%).

(iii) The presence of anti-dsDNA antibodies (2++/B), low complement levels (2+/C) or anti-Smith (Sm) antibodies (2+/C) are highly predictive of a diagnosis of SLE in patients with relevant clinical features. Anti-Ro/La and anti-RNP antibodies are less-specific markers of SLE (2+/C) as they are found in other autoimmune rheumatic disorders as well as SLE (2+/C) (SOA 95%).

(iv) aPLs should be tested in all lupus patients at baseline, especially in those with an adverse pregnancy history or arterial/venous thrombotic events (2++/B). Confirmatory tests for APS are positive LA, aCL (IgG, IgM) and/or anti-beta-2 glycoprotein-1

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

(IgG, IgM) on two occasions at least 12 weeks apart (2 ++/B) (SOA 97%).

Rationale

Clinical manifestations

SLE is a multisystem autoimmune disease [1, 8] with considerable heterogeneity. This makes the diagnosis, assessment and monitoring a challenging process [10, 26–28, 41]. Delays in diagnosis are well recognized and remain a concern [242]. Some of the most typical features and their cumulative incidence are shown in supplementary Table S3, available at *Rheumatology* Online [7, 10, 26–29]. It is important to ensure that the diagnosis of lupus is appropriate before considering treatment [41, 243]. Given the variety of clinical manifestations that can occur, lupus should be considered in the differential diagnosis of many acute and sub-acute presentations, particularly, but not exclusively, in individuals at increased risk of the disease, such as women from African, South Asian or Chinese backgrounds [2, 244]. Lupus can also affect men, resulting in severe disease, including renal involvement and greater risk of damage compared with women in some but not all reports [15, 16, 30, 31].

Renal and neurological involvement are major causes for morbidity and mortality in SLE [2, 7, 15, 16, 32, 33]. Renal disease is clinically silent and must be actively sought to prevent renal damage as discussed below. A working party of the ACR distinguished 19 NP manifestations that may occur in SLE patients [245]. Not all are directly attributable to the SLE disease process, and the true incidence of these manifestations is hard to ascertain as most of them are uncommon [23, 246]. Gastrointestinal and hepatic features occur in 39–67% of patients [42, 247] and are often not recognized as being due to lupus. As with cardiorespiratory features, they must be distinguished carefully from infection, adverse events from drugs and co-morbid conditions. Ophthalmic manifestations of lupus are rare, but potentially sight-threatening, and need careful evaluation by an experienced ophthalmologist [248–250].

Serological (immunological) manifestations

The clinical features of acute lupus are mostly due to inflammatory processes triggered by the formation of immune complexes involving autoantibodies and complement consumption, although thrombosis associated with aPLs may contribute to the pathogenesis in some patients [1, 8, 10]. With a clinical suspicion of SLE, an initial autoantibody screen should be performed. Approximately 95% of lupus patients are ANA positive, and 98% of patients will have positive ANA and/or anti-dsDNA antibodies [26, 36, 37]. ANA tests, although sensitive, are not specific for the diagnosis of lupus, and ANAs can occur in a variety of other conditions, including SS, SSc, DM, viral infections (e.g. infectious mononucleosis) and malignancy [36, 41]. The ANA test can increase in titre over time or can become negative in treated patients, and the results can vary with different assays [34, 37].

If patients have a strong clinical likelihood of having lupus, anti-dsDNA antibody testing should be done [38]. Anti-dsDNA and anti-Sm antibodies are much more specific for lupus, being very rare in other conditions [36] but they are less sensitive than ANA (supplementary Table S3, available at *Rheumatology* Online) [10, 26–29, 251]. Both the Farr and the ELISA methods are acceptable for measuring anti-dsDNA antibodies, with the former yielding higher sensitivity and specificity rates [24, 39, 40]. The *Crithidia luciliae* immunofluorescence test also has a high specificity for SLE. Additional routine serological tests are the complement C3 and C4 levels [43]. C3 generally has a higher sensitivity than serum C4 for active LN, but both tests have modest specificity and their clinical utility lies in their high negative predictive value (>90%) to exclude active disease, especially renal disease [24, 44–46].

Anti-Ro (SSA), anti-La (SSB) and anti-RNP antibodies are less specific markers for the presence of SLE, as they are found in other autoimmune rheumatic disorders [41]. Anti-Ro and anti-La are most strongly associated with primary SS but do occur in lupus patients, especially those with photosensitivity and subacute cutaneous lupus. Anti-Ro and anti-La antibodies can cause neonatal lupus syndrome including congenital heart block (CHB) in children born to mothers with these antibodies (see Recommendations for monitoring of SLE section) [64, 65]. Anti-RNP antibodies are found in overlap conditions such as MCTD [41].

All lupus patients should be tested for aPLs because their presence indicates a group at increased risk of arterial/venous thrombotic events and adverse pregnancy outcomes [241, 252, 253]. As APS and SLE often overlap, and APS sometimes evolves in to SLE, the presence of APS should also prompt assessment for lupus. Confirmatory tests for APS are positive LA, aCL (IgG, IgM), and/or anti-beta-2 glycoprotein-1(IgG, IgM) antibodies on two occasions at least 12 weeks apart [241, 252]. The LA test is the most specific of the three tests and is associated with a higher positive predictive value. The most high-risk aPL profile (triple positivity including positive LA, aCL and anti-β2-glycoprotein-I antibody) is associated with a cumulative incidence of thrombosis after 10 years of 37.1% [254].

Classification criteria for lupus

Based on the ACR (previously the American Rheumatism Association) revised criteria for SLE published in 1982 [255] and the 1997 modification [256], a patient may be classified as having SLE if they have 4 or more of 11 criteria present (Table 4). However, not all patients who meet these criteria have lupus, and not all patients diagnosed clinically with lupus have four or more of these criteria, which may appear or disappear over time [7, 33, 35, 257]. There has been a tendency to consider patients who meet the ACR classification criteria for lupus to have the disease, even if they only have certain clinical features without evidence of one or more of the immunological abnormalities that are the hallmark of this autoimmune

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

Table 4 The ACR criteria for classification of SLE[a]

Criterion	Definition
Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
Arthritis	Non-erosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling or effusion
Serositis	Pleuritis: convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion OR Pericarditis: documented by ECG or rub or evidence of pericardial effusion
Renal disorder	Persistent proteinuria >0.5 g/day or $>3+$ if quantitation not performed OR Cellular casts: may be red cell, haemoglobin, granular, tubular or mixed
Neurologic disorder	Seizures: in the absence of offending drugs or known metabolic derangements; e.g. uremia, ketoacidosis or electrolyte imbalance OR Psychosis: in the absence of offending drugs or known metabolic derangements, e.g. uremia, ketoacidosis or electrolyte imbalance
Haematologic disorder	Haemolytic anaemia with reticulocytosis OR Leukopenia $<4000/mm^3$ total on two or more occasions OR Lymphopenia $<1500/mm^3$ on two or more occasions OR Thrombocytopenia $<100\,000/mm^3$ in the absence of offending drugs
Immunologic disorder	Anti-DNA: antibody to native DNA in abnormal titre OR Anti-Sm: presence of antibody to Sm nuclear antigen OR Positive finding of aPLs on: an abnormal serum level of IgG or IgM aCL; a positive test result for LA using a standard method, or; a false positive test result for at least 6 months confirmed by *Treponema pallidum* immobilization or the fluorescent treponemal antibody absorption test
ANA	An abnormal titre of ANA by immunofluorescence, or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome

[a]The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have SLE if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation. Adapted from Tan EM *et al.* The 1982 revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 25:1271–7, copyright 1982 [255]; and Hochberg MC. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 40:1725, copyright 1997 [256], with permission from John Wiley & Sons. Anti-Sm: anti-Smith antibody.

disease. Conversely, sometimes the disease has been diagnosed on the basis of auto-antibodies and haematological features, without consideration of whether the whole clinical and serological picture is consistent with lupus being the most likely diagnosis.

To address these and some other issues, the SLICC group devised alternative classification criteria for lupus [258]. These criteria introduced a requirement for at least one clinical and one immunological criterion and two others from an expanded list of items (Table 5) compared with the ACR criteria (Table 4) [256]. They also allowed biopsy-proven LN in the presence of ANA or anti-dsDNA antibodies to be classified as lupus, without the need for other criteria [258]. The serological criteria include low complement (C3 and/or C4), as this item reflects complement consumption due to the formation of immune complexes in active lupus disease.

These revised SLICC lupus criteria have been accepted by the European Medicines Agency, the US Food and Drug Administration and NHS England as being suitable for the inclusion of patients in clinical trials and in the commissioning policy for rituximab. They are more intuitive than the previous ACR classification criteria when considering a diagnosis of lupus, and allow a larger number of patients to meet criteria; however, diagnosis should not be restricted to patients who meet the classification criteria, as they can encompass other manifestations in the appropriate serological context [259]. The SLICC criteria have been tested in a number of cohorts and in most studies have shown an increase in sensitivity and reduced specificity, so care is needed if features are better explained by an alternative diagnosis [260–263].

Conclusions

When considering a patient with a possible diagnosis of lupus, a detailed clinical history and examination is required in order to identify relevant clinical features, including assessment of haematological and renal parameters. The diagnosis should not be made without evidence of at least one autoantibody or low complement levels to support the diagnosis of this autoimmune disease, consistent with the SLICC classification criteria. The ACR (Table 4) and SLICC (Table 5) classification criteria are not diagnostic criteria but may be helpful when considering the diagnosis;

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

Table 5 Clinical and Immunologic Criteria Used in the SLICC Classification Criteria for SLE[a]

Clinical Criteria
Acute cutaneous lupus including:
lupus malar rash (do not count if malar discoid), bullous lupus, toxic epidermal necrolysis variant of SLE, maculopapular lupus rash, photosensitive lupus rash, (in the absence of dermatomyositis), or subacute cutaneous lupus, nonindurated psoriaform and/or annular polycyclic lesions that resolve without scarring, although occasionally with postinflammatory dyspigmentation or telangiectasias)
Chronic cutaneous lupus including:
classical discoid rash, localized (above the neck), generalized (above and below the neck), hypertrophic, (verrucous) lupus, lupus panniculitis (profundus), mucosal lupus, lupus erythematosus tumidus, chilblains lupus, discoid lupus/lichen planus overlap
Oral ulcers:
Palate, buccal, tongue, or nasal ulcers (in the absence of other causes, such as vasculitis, Behcet's disease, infection (herpes viruses), inflammatory bowel disease, reactive arthritis, acidic foods)
Nonscarring alopecia:
diffuse thinning or hair fragility with visible broken hairs (in the absence of other causes such as alopecia areata, drugs, iron deficiency and androgenic alopecia)
Synovitis involving two or more joints:
characterized by swelling or effusion or tenderness in 2 or more joints and thirty minutes or more of morning stiffness.
Serositis:
typical pleurisy for $>$ 1 day or pleural effusions or pleural rub or typical pericardial pain (pain with recumbency improved by sitting forward) for $>$ 1 day or pericardial effusion or pericardial rub or pericarditis by EKG (in the absence of other causes, such as infection, uremia, and Dressler's pericarditis)
Renal:
Urine protein:creatinine ratio (or 24 hr urine protein) representing 500 mg of protein/24 hr or red blood cell casts
Neurologic:
seizures, psychosis, mononeuritis multiplex (in the absence of other known causes such as primary vasculitis), myelitis, peripheral or cranial neuropathy (in the absence of other known causes such as primary vasculitis, infection, and diabetes mellitus), acute confusional state (in the absence of other causes, including toxic-metabolic, uremia, drugs)
Hemolytic anemia
Leukopenia: $<$ 4000/mm^3 at least once (in the absence of other known causes such as Felty's, drugs, portal hypertension) OR
Lymphopenia: $<$ 1000/mm^3 at least once (in the absence of other known causes such as corticosteroids, drugs and infection)
Thrombocytopenia: $<$100,000/mm^3 at least once (in the absence of other known causes such as drugs, portal hypertension, TTP)
Immunologic Criteria
ANA level above laboratory reference range
Anti-dsDNA antibody level above laboratory reference range (or $>$ 2 fold the laboratory reference range if tested by ELISA)
Anti-Sm
Antiphospholipid antibody:
any of the following: lupus anticoagulant, false-positive rapid plasma regain (RPR), medium or high titer, nticardiolipin antibody level (IgG, IgM or IgA), anti-β_2 glycoprotein I (IgG, IgM or IgA)
Low complement:
low C3, low C4, low CH50
Direct Coombs' test (in the absence of hemolytic anemia)

[a]Patients can be classified as having SLE if they satisfy four of the clinical and immunological criteria, including at least one clinical criterion and one immunologic criterion, OR if they have biopsy-proven nephritis compatible with SLE in the presence of ANAs or anti-dsDNA antibodies. Reproduced from Petri M *et al.* Derivation and validation of the Systemic Lupus International Collaborating Clinics classification criteria for systemic lupus erythematosus. Arthritis Rheum 64:2677–86. Copyright 2012. With permission from John Wiley & Sons [258]. TTP: thrombocytopaenic purpura; anti-Sm: anti-Smith antibodies.

however, they do not cover all the clinical manifestations of lupus. The LOEs and GORs for parameters supporting the diagnosis of lupus are shown in Table 1.

Recommendations for the assessment of SLE patients

(i) Clinical manifestations in SLE patients may be due to disease activity, damage, drug toxicity or the presence of co-morbidity. In the case of disease activity, it is important to ascertain whether this is due to active inflammation or thrombosis, as this will define treatment strategies (LOE 2++, GOR B, SOA 97%).

(ii) Clinical assessment of a lupus patient should include a thorough history and review of systems, full clinical examination and monitoring of vital signs, urinalysis, laboratory tests, assessment of

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

health status and quality of life, and measurement of disease activity and damage using standardized SLE assessment tools (2++/B). Imaging (4/D), renal (2++/B) and other biopsies (4/D) should be performed where indicated (SOA 100%).

(iii) Disease activity is categorized into mild, moderate and severe, with the occurrence of flares (2+/C). Mild disease activity is clinically stable lupus with no life-threatening organ involvement, mainly manifesting as arthritis, mucocutaneous lesions and mild pleuritis. Patients with moderate disease activity have more serious manifestations, and severe disease is defined as organ- or life-threatening (4/D) (SOA 93%).

Rationale

Assessment of lupus

A systematic approach should be taken because of the diversity and complexity of clinical and laboratory manifestations (supplementary Table S3, available at *Rheumatology* Online) [264–266]. Clinical manifestations may be due to one or any combination of the following: disease activity from active inflammation or thrombosis, acute drug toxicity, chronic damage due to the effects of the disease or its treatment (such as lung fibrosis or atherosclerosis), or co-morbidity (e.g. infection). It is important to take a detailed history and to perform a clinical examination, including vital signs and urinalysis, to establish the likely differential diagnoses and then to organize the relevant investigations as suggested in Table 6, depending on the circumstances. In addition, when assessing disease activity with a view to planning treatment, it is necessary to determine the circumstances that may have led to a lupus flare (such as exposure to sunlight, concurrent or recent infection, hormonal changes, or timing of previous disease-related therapeutic change) as this will guide further investigation, treatment change (including non-drug measures) and disease monitoring required thereafter.

Validated instruments for the assessment of lupus

The most reliable way of assessing disease activity is to use a defined instrument for this purpose that has been validated and is available with an appropriate glossary and scoring instructions [265, 266]. For example, the NHS England Interim Clinical Commissioning Policy Statement for rituximab in lupus published in 2013 [267] recommended the use of two lupus-specific disease activity indices: the BILAG index and the SLEDAI. For such purposes, the currently recommended revised versions are the BILAG-2004 index [268, 269] (for BILAG-2004 index data collection form, glossary and scoring see supplementary data, available at *Rheumatology* Online) and SLEDAI-2K [270] or the SELENA-SLEDAI [271, 272] (see supplementary data, available at *Rheumatology* Online, for SLEDAI-2K and SELENA-SLEDAI index data collection forms). Modifications have been made for use in pregnancy [273, 274]. For optimal performance, training in the use of these instruments is advised. It is essential that only manifestations/items due to SLE disease activity are recorded and that the data collection forms are used in conjunction with the appropriate glossary and scoring rules. There is one validated instrument for assessing damage, the SLICC/ACR Damage Index (SDI) [275]. It is recommended that patients' assessment of their disease be captured using health status or quality of life questionnaires such as the generic Short-form36 (SF-36), which has been validated for use in lupus patients [276], or a lupus-specific questionnaire such as the Lupus Quality of Life (LupusQoL) [277]. There is agreement that for best practice these instruments should be used [74, 278], although there are no data confirming that their use improves the outcomes for patients. Better outcomes are achieved if lupus in-patients are managed in centres with experience in managing lupus [279–282].

Definitions of mild, moderate and severe lupus

For the purpose of planning appropriate treatment, disease activity has been broadly categorized as mild, moderate or severe [8], and worsening disease activity is termed flare, which can be similarly categorized as mild, moderate or severe [283, 284]. Examples are shown in Table 7. The term mild disease activity reflects clinically stable disease with no life-threatening organ involvement and that is not likely to cause significant scarring or damage. Examples of scores for such patients when using formal assessment tools would include a SLEDAI-2K score of <6 [270] and/or one BILAG B score [269]. Patients with moderate disease have more serious manifestations, which if left untreated would cause significant chronic scarring. Examples of scores for such patients when using formal assessment tools would include a SLEDAI-2K score in the range of 6–12 [270] and/or two or more BILAG B scores [269]. Severe disease is defined as organ or life threatening and reflects the most serious form of systemic disease that requires potent immunosuppression. Examples of scores for such patients when using formal assessment tools would include a SLEDAI-2K score of >12 [270] and/or at least one BILAG A score [269].

Conclusions

The assessment of a patient with lupus, as with making the initial diagnosis, is dependent on a careful history and examination of the patient, with relevant haematological, biochemical and immunological testing as well as other investigations as necessary (shown in Table 6) to establish the degree of disease activity and accumulation of chronic damage, and to identify other complications or co-morbid conditions that will influence the treatment plan. The LOEs and GORs for the components of the assessment and monitoring of lupus disease are shown in Table 1.

Recommendations for monitoring of SLE

(i) Patients with lupus should be monitored on a regular basis for disease manifestations, drug toxicity and co-morbidities (LOE 2++, GOR B, SOA 99%).

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

Table 7 SLE treatment strategies for examples of mild, moderate and severe lupus

Item	Mild activity/flare BILAG C scores or single B score; SLEDAI <6	Moderate activity/flare BILAG 2 or more systems with B scores, SLEDAI 6–12	Severe activity/flare (non-renal) BILAG 1 or more A scores; SLEDAI >12
Typical manifestations attributed to lupus	Fatigue, malar rash, diffuse alopecia, mouth ulcers, arthralgia, myalgia, platelets 50–149 $\times$ 10^9/l	Fever, lupus-related rash up to 2/9 body surface area, cutaneous vasculitis, alopecia with scalp inflammation, arthritis, pleurisy, pericarditis, hepatitis, platelets 25–49 $\times$ 10^9/l	Rash involving >2/9 body surface area, myositis, severe pleurisy and/or pericarditis with effusion, ascites, enteritis, myelopathy, psychosis, acute confusion, optic neuritis, platelets <25 $\times$ 10^9/l
Initial typical drugs and target doses if no contraindications	CSs[a]: topical preferred or oral prednisolone $\leqslant$20 mg daily for 1–2 weeks or I.m. or IA methyl-prednisolone 80–120 mg and HCQ $\leqslant$6.5 mg/kg/day and/or MTX 7.5–15 mg/week and/or NSAIDs (for days to few weeks only)	Prednisolone[a] $\leqslant$0.5 mg/day or i.v. methyl- prednisolone $\leqslant$250 mg $\times$ 1–3 or i.m. methyl-prednisolone 80–120 mg and AZA 1.5–2.0 mg/kg/day or MTX 10–25 mg/week or MMF 2–3 g/day or ciclosporin $\leqslant$2.0 mg/kg/day and HCQ $\leqslant$6.5 mg/kg/day	Prednisolone[a] $\leqslant$0.5 mg/day and/or i.v. methyl-prednisolone 500 mg $\times$ 1–3 or prednisolone $\leqslant$0.75–1 mg/kg/day and AZA 2–3 mg/kg/day or MMF 2–3 g/day or CYC i.v. or ciclosporin $\leqslant$2.5 mg/kg/day and HCQ $\leqslant$6.5mg/kg/day
Aiming for typical maintenance drugs/doses providing no contraindications	Prednisolone[a] $\leqslant$ 7.5 mg/day and HCQ 200 mg/day and/or MTX 10 mg/week	Prednisolone[a] $\leqslant$7.5 mg/day and AZA 50–100 mg/day or MTX 10 mg/week or MMF 1 g/day or ciclosporin 50–100 mg/day and HCQ 200 mg/day;	Prednisolone[a] $\leqslant$7.5 mg/day and MMF 1.0–1.5 g/day or AZA 50–100 mg/day or ciclosporin 50–100 mg/day and HCQ 200 mg/day;
	Aim to reduce and stop drugs except HCQ eventually when in stable remission	Aim to reduce and stop drugs except HCQ eventually when in stable remission	Aim to reduce and stop drugs except HCQ eventually when in stable remission

[a]The lowest effective dose of prednisolone or other CSs should be used at all times.

(ii) Those with active disease should be reviewed at least every 1–3 months (2+, C/D), with blood pressure (1+/A), urinalysis (1+/A), renal function (1+/A), anti-dsDNA antibodies (2++/B), complement levels (2+/C), CRP (2+/C), full blood count (3/C), and liver function tests (4/D) forming part of the assessment, and further tests as necessary (4/D). Patients with stable low disease activity or in remission can be reviewed less frequently, for example, 6–12 monthly (4/D) (SOA 99%).

(iii) The presence of aPLs is associated with thrombotic events, damage, and adverse outcomes in pregnancy (2++/B). If previously negative, they should be re-evaluated prior to pregnancy or surgery, or in the presence of a new severe manifestation or vascular event (4/D) (SOA 96%).

(iv) Anti-Ro and anti-La antibodies are associated with neonatal lupus (including CHB) and should be checked prior to pregnancy (1+/A) (SOA 100%).

(v) Patients with lupus are at increased risk of comorbidities, such as atherosclerotic disease, osteoporosis, avascular necrosis, malignancy and infection (2+/C). Management of modifiable risk factors, including hypertension, dyslipidaemia, diabetes, high BMI and smoking, should be reviewed at baseline and at least annually (4/D) (SOA 98%).

(vi) Immunosuppressive therapy may lead to toxicities. Close monitoring of drugs by regular laboratory tests and clinical assessment should be performed in accordance with drug monitoring guidelines (4/D) (SOA 98%).

Rationale

Frequency of monitoring lupus/follow-up visits

There are no randomized controlled trials (RCTs) comparing different monitoring strategies in terms of frequency and details of assessments performed; however, data from various cohort studies have informed our expert opinion and previous guidelines in this respect [22, 71, 74, 278]. Patients should be told to report to clinicians if they develop any new or significant worsening of clinical manifestations. In most patients with active clinical disease, clinic visits should be approximately every 4 weeks initially, reducing gradually down to about 3-monthly reviews as the disease comes under control. There remains a significant risk of flare and the development of damage, even for patients who achieve early remission [72]. For most patients with mild features, including those who are clinically quiet but serologically active, 3-monthly visits are adequate [77]. Review should become more frequent if the disease becomes more active, especially if there is renal involvement,

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

as the patients will require clinical, renal and serological evaluation (see below) [285]. For patients with inactive disease, without previous renal involvement or organ damage (that can predict increased risk of further active disease and damage), review may be less frequent, for example every 6 months providing treatment is stable and suitable drug monitoring is in place [74]. Patients should be seen more regularly, however, if treatment is being withdrawn or has been stopped, due to the risk of disease flare, even if they appear to be in remission [72].

Reasons for clinical monitoring in lupus patients

Regular monitoring of clinical and laboratory features of active disease should take place, with additional investigations as necessary (Table 6), to assess and monitor changes in disease activity, the development of chronic damage, and to detect the presence of (and changes in) co-morbid conditions that may be confused with lupus (such as FM, hypothyroidism, iron deficiency anaemia, infection), and drug-induced conditions [22, 74, 265]. LOEs for the laboratory parameters are shown in Table 1. Proteinuria (and renal function in particular [24]), high DAS [16, 48, 73, 286], new and different types of cutaneous lesions [50], arthritis [72], NP disease [16, 51] and cytopenias [52, 53] have been shown to correlate with disease severity and can predict future flares and the development of damage [11, 32, 49, 54, 55]. Only measurement of proteinuria and renal function have been shown to have strong predictive value for outcome [22, 24, 56]. Chest X-ray, ECG and other specific tests such as lung function, echocardiography and neurophysiology should be repeated during the course of the disease as necessary. When major organs are involved, additional imaging (such as brain MRI) and pathology (renal/skin biopsy) can add significant prognostic information, particularly renal biopsy, and may need to be repeated to assess response to treatment [22–24, 287, 288].

Interpretation of haematological, renal and other biochemical parameters

Lymphopenia is a common manifestation of lupus (supplementary Table S3, available at *Rheumatology* Online), and some patients will have leucopenia and neutropenia regularly with active disease [53]. This needs to be remembered when monitoring patients on cytotoxic therapy, as a fall in cell counts may signify the need to increase therapy for lupus rather than reduce or discontinue therapy if drug toxicity is suspected. It also means that the usual drug-monitoring limits of tolerance may need to be reviewed and personalized in the context of an individual with SLE. Thrombocytopenia may be acute and indicative of a disease flare, or low grade and chronic as part of of lupus and/or associated with APS [57].

ESR is often raised in active SLE [70], but can also reflect persistent polyclonal hypergammaglobulinaemia, and is not a reliable marker of disease activity. CRP is usually normal [66–68] or slightly elevated in the presence of serositis or arthritis [69]. A significantly raised CRP is more likely to indicate infection, and patients with raised CRP will need therefore to be thoroughly screened for infection, given that infection is the commonest cause of death in lupus patients. In contrast, a raised ESR does not discriminate between active lupus and infection [69]. Immune complexes of CRP and anti-CRP antibodies may form in lupus patients, possibly explaining the low levels of CRP observed with active disease [67].

Proteinuria should be quantified using the urine protein:creatinine ratio or 24-h urine collection. Microscopic examination of the urine to look for red cells and red cell casts is useful for identifying active renal disease and renal flares, but the assessment of casts is now rarely done [24, 289, 290]. When assessing haematuria, it is important to exclude infection, menstrual blood loss and calculi. White cells in the urine are most often due to urine or vaginal infection and can be hard to interpret, but as an otherwise unexplained finding, are associated with active tubulointerstitial inflammation.

Serum immunoglobulins should be measured prior to starting drugs such as MMF, CYC and rituximab which have the most risk of inducing immunoglobulin deficiency that might increase the risk of infection. The initial repeat measurement of the serum immunoglobulins should take place about 3–6 months later and can then be spaced out to annual checks [74, 199, 291, 292, 293]. Specific antibodies, for example, pneumococcal antibodies, may be assessed (if tests are available) to assess the need for and response to immunization. Screening for chronic infections (such as TB, hepatitis B and C, HIV, HPV) is recommended before starting immunosuppressants and repeated if reactivation of infection is suspected.

It is important to measure creatinine kinase at baseline and to continue to follow it in patients with myositis or myalgias that might be due to lupus or statins used to prevent atherosclerosis [75]. Monitoring of cholesterol and of other lipids, and remaining vigilant for and treating the development of diabetes mellitus and features of the metabolic syndrome (which may increase cardiovascular risk, particularly in patients on glucocorticoids), are important and should be as successful as in the general population [71, 74, 76]. Additional monitoring investigations should include Vitamin D3, which is often low as a consequence of sun avoidance and/or chronic kidney disease [294]. Vitamin D is required for optimal bone health, especially in patients on chronic glucocorticoid therapy and/or following the menopause [295]. Clinicians should have a low threshold for assessing thyroid function, as hypothyroidism can present with similar features to lupus; it co-exists with lupus in ~7% of patients, and thyroid antibodies are found in 14% [296–298].

Monitoring of lupus autoantibodies and complement

Serial anti-dsDNA antibodies and C3 and C4 levels are useful because rising, high anti-dsDNA antibodies and falling, low complement levels are associated with flare [49, 58], particularly in patients with LN [24]. In general, concomitantly rising anti-dsDNA titres [39, 43, 46, 49, 59, 60] and decreasing C3 and/or C4 levels [43–46] are more important predictors of current or impending flares than the absolute levels, and levels of anti-dsDNA antibodies may actually fall at the time of flare [299].

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

It can be helpful to combine a sensitive but less specific anti-dsDNA antibody assay (e.g. ELISA) with one that only measures more specific, high affinity or high avidity antibodies (such as Farr radioimmunoassay or the *Crithidia* test), because only tests measuring high affinity and high avidity antibodies are strongly associated with renal disease; however, other ELISAs can be used to monitor disease activity [40]. Stable active serology without clinical features does not necessarily warrant therapy [71], but patients need to be followed closely, with individual care decisions made to prevent over- or undertreatment. Many physicians would avoid reducing therapy in this situation as patients may develop renal disease [300], but the serological tests do not always predict flare [61, 62, 71]. About 40% of lupus patients do not have anti-dsDNA antibodies, so for this group of patients, they are not useful for monitoring disease activity [63]. Some patients are heterozygous for the C4 allele and due to a null allele have a persistently low C4 level (at about 50% of normal), without having active disease, but C4 levels can still fluctuate with disease activity.

ANA, anti-Sm and anti-RNP antibodies tests should be carried out at baseline and do not need to be repeated at each visit, as levels do not fluctuate with disease activity. Anti-Ro and anti-La antibodies should be measured in women planning pregnancy or in early pregnancy, as they may be transferred across the placenta and are associated with CHB in ~1–2% of babies [64, 65]. Fetal heart-rate monitoring should be instituted from week 16 of pregnancy and continued throughout pregnancy in women with either of these antibodies. Neonatal lupus rash develops in ~10% of babies born to mothers with these antibodies (especially if exposed to UV light), and laboratory abnormalities (cytopenias and abnormal liver function tests) have also been observed in babies exposed to these antibodies [64].

aPLs should be assessed at baseline and, if previously negative, they should be re-evaluated in the presence of a new vascular event, adverse pregnancy outcome or other new manifestation that might have a thrombotic component, as well as prior to a planned pregnancy [47, 241, 252, 253]. Positive tests for APS include LA, aCL (IgG, IgM) and/or anti-beta-2 glycoprotein 1(IgG, IgM), and these tests should be repeated after 12 weeks to confirm positivity [241, 252], although LA cannot be evaluated if anticoagulation has been started, as this would interfere with the assay.

Monitoring for the development of co-morbidities

Patients with lupus are at increased risk of co-morbidities [71, 74], such as infection, premature cardiovascular and peripheral vascular disease, osteoporosis, avascular necrosis and some malignancies (non-Hodgkin's lymphoma, cervical, vulval, lung and thyroid cancer [301, 302]). The management of these issues is beyond the scope of this guideline and should follow national/international guidelines for each condition and include appropriate vaccinations [22, 71, 74, 278]. Nevertheless, screening for and managing these conditions is an integral part of the assessment and regular monitoring of lupus patients, as described in the EULAR recommendations for monitoring patients with SLE in clinical practice and in observational studies [74]. A preventative approach should be adopted, since the commonest causes of death in lupus patients in the UK are infection and cardiovascular disease, followed by malignancy [15, 16, 18]. Modifiable risk factors for co-morbidities to address include vaccination status, hypertension, dyslipidaemia, diabetes, high BMI and smoking. These should be reviewed at baseline and at least annually thereafter [22, 24, 71, 74]. These co-morbidities may occur at a younger age than in the normal population, and clinicians should screen regularly for them, even though there are no RCTs to suggest that more intense screening than that applied in the general population improves outcome in lupus patients [22, 24, 71, 74]. Routine cancer screening (particularly for cervical cancer, given the increased risk of HPV infection in lupus patients [303]) should not be forgotten due to emphasis on lupus disease management [304].

Monitoring of drugs

This should be similar to that for drugs used in other rheumatic diseases, but due to the occurrence of cytopenias and abnormal renal and liver function possibly caused by lupus disease itself, monitoring tests may need to be undertaken more frequently, and the interpretation of laboratory results is more difficult. Adherence to drugs may be confirmed by measuring drug levels (e.g. of ciclosporin, tacrolimus, mycophenolate [171] and HCQ [80]), but these tests are not widely available (except that for tacrolimus, which is tested in order to guide optimal dosing and to prevent renal toxicity). There is little lupus-specific data about target drug levels, and detailed discussion is beyond the scope of these recommendations, but this topic has been reviewed for rheumatic diseases in general [78] as well as for lupus [305]. It should be noted that, like other chronic conditions, adherence levels are suboptimal in lupus, and therefore specific consideration of this issue is needed in patients showing poor response to therapy [79].

Conclusions

It is important to monitor lupus patients regularly to assess and monitor changes in disease activity, chronic damage, and in drug-induced and co-morbid conditions that may be confused with lupus and that are associated with an increased risk of death. The LOEs and GORs for the main components of monitoring of lupus patients are shown together in Table 1, and a suggested protocol is shown in Table 6.

Recommendations for the management of mild SLE

(i) Treatments to be considered for the management of mild non-organ-threatening disease include the disease-modifying drugs HCQ (1++/A) and MTX (1+/A), and short courses of NSAIDs (3/D) for symptomatic control. These drugs allow for the avoidance of or dose reduction of CSs (SOA 94%).

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

(ii) Prednisolone treatment at a low dose of $\leqslant$7.5 mg/day may be required for maintenance therapy (2+/C). Topical preparations may be used for cutaneous manifestations, and IA injections for arthritis (4/D) (SOA 93%).
(iii) High–Sun Protection Factor (SPF) UV-A and UV-B sunscreen are important in the management and prevention of UV radiation–induced skin lesions (2++/B). Patients must also be advised about sun avoidance and the use of protective clothing (4/D) (SOA 97%).

Rationale

Overview of treatment of mild lupus

Mild lupus features (Table 7) are distressing for patients and warrant treatment to relieve symptoms and signs. Such treatment may prevent progression to severe manifestations requiring more intense immunosuppression. These manifestations can be managed with CSs, HCQ and other antimalarials, MTX, NSAIDs and sunscreens. The LOEs and GORs for the drugs used to treat lupus disease are summarized in Table 2, and the SOAs with the recommendations are above. There are little data to support the use of topical therapies, dapsone, retinoids, thalidomide or danazol in the treatment of refractory cutaneous lupus rashes and vasculitis, and as these drugs are not used for other systemic features of lupus, they are not discussed here but have been reviewed [287, 288].

CSs for mild lupus

Summary

Topical preparations should be used initially for cutaneous manifestations, and intra-articular (IA) or intramuscular (i.m.) injections of CSs for arthritis. Short courses of oral prednisolone (up to 20 mg/day) are used for short periods of time (up to 14 days and reduced rapidly) to induce remission in some cases of mild lupus where local treatment is not sufficient or practical (evidence discussed below in moderate lupus). Prednisolone can be used in women who are trying to conceive, are pregnant or are breast-feeding [239].

Evidence

There are no RCTs comparing different types of CS administration, such as skin creams and ointments, intralesional, IA and i.m. injections, and oral CS drugs (usually prednisolone in the UK). CSs contribute to the development of chronic damage and co-morbidities such as cataracts, osteoporotic fractures, diabetes, atherosclerosis and infection [12, 14]. It has been shown that a 1 mg/day increase in maintenance prednisone dose is associated with a 2.8% increase in the risk of new organ damage, and that prednisolone dosing of $\leqslant$7.5 mg/day is associated with less risk of cataracts, osteoporotic fractures and cardiovascular damage than higher doses [306].

Conclusions

The lowest possible dose/amount of CSs should be used due to their side effects, including the risk of contributing to chronic damage and infection. Prednisolone treatment at a low dose of $\leqslant$7.5 mg/day may be required for maintenance therapy and has less risk of side effects than higher doses (2+/C).

HCQ and other anti-malarial agents

Summary

There is good evidence (Table 2) for the efficacy and safety of HCQ, the most commonly prescribed anti-malarial agent and one of the few licensed drugs for lupus. Providing that the patient has normal renal and liver function, HCQ can be used at doses of up to 6.5 mg/kg/day and is compatible with pregnancy and breast-feeding. It is used (Table 7) for skin and joint involvement, myalgia, fever, fatigue, pleurisy, to reduce the development of renal disease and chronic damage [14, 121] and for its steroid-sparing properties (even in patients with more severe disease) [71]. Chloroquine is used if HCQ is not available or not tolerated; however, there is less evidence for benefit and it has a greater risk of retinal toxicity than HCQ [121]. Mepacrine (quinacrine) is used predominantly for cutaneous lupus and has the least risk of ocular toxicity [287, 307–309].

Evidence

The benefits of anti-malarials on lupus activity were reported in four RCTs [81–84], five prospective cohort studies [87–91], three retrospective cohort studies [92–94] and an open-label extension of the first RCT [95]. There have been two other double-blind RCTs confirming that lupus rashes significantly improve with HCQ [85] and chloroquine [86]. The cohort studies have shown that response often takes 3–4 months [94], but at 6 months only 60% of patients with discoid rash show some response [94]. Another study showed that 20% of patients with an adequate response lose it within 2 years and need other therapies [310]. Higher drug levels were associated with increased cutaneous response in a prospective study [311]. In a double-blind RCT [80], low drug levels were associated with increased disease activity. Systemic features and smoking are also associated with an increased risk of poor response [94, 96, 122].

Many of the studies showing increased flare rates in patients who discontinued HCQ involved pregnant patients. A RCT in lupus patients [84] and two prospective [87, 90] cohort studies support the use of this drug before conception and in pregnancy to reduce flares in the mother. Although HCQ can cross the placenta, exposure is not associated with significant adverse effects on the fetus [87, 90, 97–100]. HCQ has anti-thrombotic as well as anti-inflammatory properties and by reducing disease activity in the mother may improve the outcome for the child by improving placental function [101, 102]. There is increasing evidence that HCQ reduces the risk of CHB in babies born to mothers with anti-Ro antibodies [103, 312, 313]. Further evidence supporting the use of HCQ in pregnant women as well as in those planning pregnancy and breast-feeding is reviewed in the BSR Guidelines on drugs in pregnancy in the rheumatic diseases [239].

There is further evidence from high-quality prospective and retrospective cohort studies that patients treated with anti-malarials (particularly HCQ) not only have lower levels

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

of overall lupus activity and reduced rates of flare [80, 81, 84, 89, 90, 95], but can be managed with lower doses of CSs [83, 84, 90, 104]. The patients are more likely to stay clinically quiescent if HCQ is continued when the disease goes in to remission [105]. Patients on MMF are more likely to achieve renal remission if treated with HCQ [93]. Patients on HCQ are less likely to develop serious renal disease and have delayed time to renal damage [104], lower frequency of seizures [106] and less NP damage [107], greater delay in integument damage [108], less overall damage [109, 110] and, most importantly, improved survival [111, 112]. Some of the benefits on survival may be mediated by the beneficial effects of anti-malarials on total cholesterol, LDL-cholesterol, triglycerides, glucose [113] and/or by the prevention of thrombosis [101, 102, 121] and atherosclerotic plaque formation [114].

Patients take HCQ on average for about 6 years [115–118]. In general HCQ is well tolerated and better tolerated than chloroquine [86, 115, 116, 121]. The commonest adverse effects of anti-malarials are gastrointestinal, but a few patients stop because of headache, dizziness, itching, rash, non-retinal eye problems, hearing loss, myopathy or other rare neuromuscular side effects [121, 287]. The most serious adverse events are cardiac (which are very rare) [119] and retinopathy (which is more common with chloroquine than HCQ) [121, 314]. Retinopathy is unpredictable but unlikely with <7 years treatment with HCQ. It is more common thereafter [120] and with doses of HCQ above 6.5 mg/kg/day, or renal or liver impairment. It requires active screening to detect it early when it is asymptomatic and is most likely to be reversible [120, 314]. Policies on screening for ocular toxicity vary between countries and local guidelines should be followed [314, 315]. In general in the UK, baseline and yearly optician eye tests are recommended initially, with more detailed ophthalmological screening after 5 years of therapy [316].

Conclusions

There are good data from two systematic reviews and a meta-analysis including 7 RCTs and 36 cohort studies supporting the use of HCQ in lupus patients to reduce disease activity and as a steroid-sparing agent: overall LOE 1++, GOR A. HCQ should be given to all patients with mild lupus to prevent flares, the development of damage and to improve survival. It is recommended that HCQ be continued or started, even in those developing disease severe enough to warrant immunosuppressive therapies, including LN [22, 24, 25]. However patients with renal or liver dysfunction should have the dose reduced [314]. It is compatible with conception, pregnancy and breast-feeding. Unfortunately, it has a long half-life and takes at least 2 months to be effective [287, 309]. Patients need to be warned about this or they may discontinue the drug prematurely.

MTX in mild SLE

Summary

Although not licensed for the treatment of lupus, low-dose weekly MTX ($\leqslant$25 mg/week) has been used to reduce mild and moderate disease activity in lupus, particularly to control inflammatory arthritis and lupus skin rashes, originally on the basis of a variety of case series and cohort studies [317, 318]. MTX was originally used in patients who had failed HCQ and low-dose CSs, but it can be used with HCQ to avoid CSs or to promote CS dose reduction. Caution has been advised on the use of MTX in patients with LN, particularly as those with renal impairment will be at increased risk of MTX toxicity [317]. It is contra-indicated in women trying to conceive or pregnant as it is teratogenic. For these patients AZA would be more suitable (see section on moderate lupus for evidence).

Evidence

A systematic review by Sakthiswary and Suresh [319] summarizes the data from three controlled trials (two double-blind, placebo-controlled trials [123, 124], and a controlled open-label trial comparing MTX and chloroquine [125]) and five observational studies (two open-label prospective studies [126, 127]; a cross-sectional study [128]; a retrospective case–control cohort study [129]; and an open-label controlled study [130]). Another systematic review [133] includes two additional case series [131, 132]. These studies support the use of MTX to reduce mild and moderate lupus disease activity, and some demonstrated steroid-sparing properties. Some of these studies showed benefit specifically in treating lupus arthritis, rashes, vasculitis, serositis, myositis and constitutional symptoms, but there was little change in ESR, anti-dsDNA antibodies, C3 or C4 levels, except in a study with longer duration than previous studies [130]. The reduction in SLEDAI in the five controlled studies reporting these data included in the systematic review [319] was calculated to have an odds ratio = 0.444 (95% CI: 0.279, 0.707; $P = 0.001$). The analysis of the four controlled studies reporting steroid-sparing properties for MTX provided an odds ratio = 0.335 (95% CI: 0.202, 0.558; $P = 0.001$). Side effects led to discontinuation in $\sim$10% of patients but were not serious. It is teratogenic and should not be used in women within 3 months of planning to conceive, or who are pregnant or breast-feeding [239], nor in patients with renal impairment, because reduced renal function increases the risk of adverse events, particularly bone marrow suppression.

Conclusions

There are good data from two systematic reviews including three RCTs and seven cohort studies supporting the use of MTX in lupus to reduce disease activity and as a steroid-sparing agent: overall LOE 1+, GOR A.

NSAIDs in mild SLE

Summary

There are no RCTs of NSAIDs in SLE. Publications support the cautious use of NSAIDs for short periods of time for symptom control in SLE (inflammatory arthralgia, myalgia, chest pain and fever) where potential benefit outweighs the known risks of NSAIDs and paracetamol has been insufficient or not tolerated. The risk of NSAID-induced acute renal failure is increased in patients with LN, so NSAIDs

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

should be avoided in patients with renal involvement. NSAID-induced allergic reactions, aseptic meningitis, cutaneous reactions and hepatotoxicity are increased in SLE patients. Caution is required in pregnancy [240].

Evidence

A review of the literature on non-selective Cox inhibitors and selective Cox-2 inhibitors [320] highlighted the potential increased risk of renal, hepatic and neurological toxicity in lupus patients. A retrospective case series assessing celecoxib, with a detailed literature review of NSAIDs [321] and a more comprehensive systematic review addressing the risk–benefit ratio of non-selective and selective inhibitors of cyclooxygenases in SLE patients, were published subsequently [134]. More recently it has become clear that NSAIDs (except possibly naproxen) can predispose to acute myocardial infarction in individuals with coronary heart disease [322], which is an additional reason for caution in lupus patients.

Conclusions

Based on one systematic review of the evidence from case series and case reports, the overall LOE for NSAIDs in non-renal mild lupus is three and GOR is D.

High-SPF UV-A and UV-B sunblock in SLE

Summary

There is clear evidence that ultraviolet radiation (UV-A and UV-B) can induce various forms of cutaneous lupus [287]. Patients with systemic lupus without cutaneous features have also been found to have an abnormal reaction to UV irradiation [323].

Evidence

Sunscreens were shown to prevent discoid and subacute cutaneous lupus rashes in a case series [141] and to reduce systemic features such as renal disease, thrombocytopenia and hospitalization in a cohort study [136]. Three open-label controlled trials [137–139], a retrospective case series [140] and a double-blind, controlled trial [135] have shown that sunscreens that block UV-A and UV-B can reduce UV radiation–induced lesions of cutaneous lupus.

Conclusions

Lupus patients should be advised about avoidance of sun and other sources of UV irradiation, and about the use of sunscreens (UV-A protection five stars and UV-B protection from SPF factors 30 to 50 products, which can be prescribed on the NHS) and protective clothing. Overall, the LOE is 2++ for sunscreens (one small RCT and six other studies) in lupus patients to prevent cutaneous lesions, and the GOR is B.

Recommendations for the management of moderate SLE

(i) The management of moderate SLE involves higher doses of prednisolone (up to 0.5 mg/kg/day) (2+/C), or the use of i.m. (4/D) or i.v. doses of methylprednisolone (MP) (2+/C). Immunosuppressive agents are often required to control active disease and are steroid-sparing agents (2+/C). They can also reduce the risk of long-term damage accrual (4/D) (SOA 98%).

(ii) MTX (1+/A), AZA (2+/C), MMF (2++/B), ciclosporin (2+/C) and other calcineurin inhibitors (3/D) should be considered in cases of arthritis, cutaneous disease, serositis, vasculitis or cytopaenias if HCQ is insufficient (SOA 97%).

(iii) For refractory cases, belimumab (1+/B) or rituximab (2+/C) may be considered (SOA 98%).

Rationale

Overview of the management of moderate lupus

Immunosuppressive cytotoxic agents should be used with CSs, while continuing anti-malarials and avoidance of UV radiation, to reduce disease activity in moderate lupus (Table 7), prevent the risk of further flares and lower the risk of damage accrual due to disease and CSs, because they act as steroid-sparing agents. Despite their widespread use in clinical practice and as background standard of care therapy in clinical trials, there are only a few RCTs demonstrating the efficacy of CSs and other immunosuppressive agents for the management of moderate lupus. Additional drugs should be considered if HCQ is insufficient or not tolerated and can be used in addition to HCQ. The evidence supporting the use of MTX has been discussed above, and the evidence supporting the use of CSs, AZA, MMF, calcineurin inhibitors (ciclosporin and tacrolimus) and LEF are discussed in this section. For patients who do not respond to these drugs, the biologic drugs rituximab and belimumab may be considered. It should be noted that there is a specific NHS England 2013 Interim Clinical Commissioning Policy Statement for rituximab in adult SLE patients [267], and NICE guidance for the use of belimumab in active autoantibody-positive SLE in adults has been published in 2016 [324]. Patients being considered for these drugs should be discussed with and/or seen by a specialist lupus centre with experience in using these drugs. The patients should meet specific criteria and be entered in to the BILAG Biologics Register (see below and Fig. 1). For patients not requiring biologics, suggested initial target dosing regimens for active disease (as used in most studies) and lower maintenance dosing regimens to prevent recurrence of disease once patients are stable are shown in Table 7. The actual regimen used for individual patients will depend on the clinical picture and the treatment history. It is important to increase the dose and/or change treatment if patients fail to respond in the expected time frame. The LOEs and GORs for all the drugs used to treat lupus are summarized in Table 2.

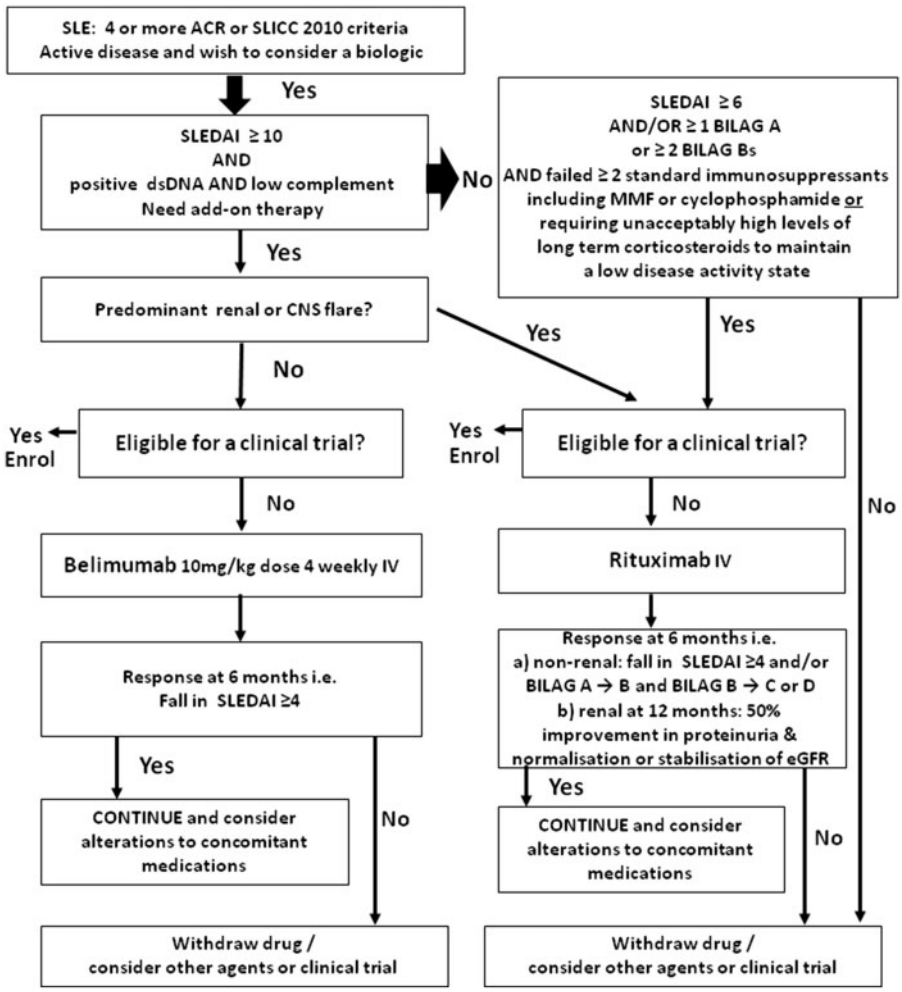
CSs for moderate lupus

Summary

Higher doses of oral CSs are required initially than are required for mild lupus, for example prednisolone at up

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

FIG. 1 Summary of NICE and NHS England guidance for the use of belimumab and rituximab in patients with SLE



Belimumab is licensed and NICE-approved (Belimumab for active autoantibody-positive systemic lupus erythematosus: TA397, published June 2016) and should be considered first [324]. Rituximab is not licensed and should only be used according to the NHS England Interim Clinical Commissioning Policy Statement: rituximab for the treatment of systemic lupus erythematosus in adults: published September 2013 A13/PS/a [267]. All patients receiving either drug must be enrolled in the BILAG Biologics Register and be managed at or in collaboration with a specialized centre.

to 0.5 mg/kg/day, and intermittent treatment with i.m. 80–120 mg MP or even i.v. doses of MP (up to 250 mg) are used as well as, or instead of, oral prednisolone to promote a quicker response with less total CS exposure. Prednisolone dosing should be reduced, as disease activity improves, to the lowest possible maintenance dose and stopped, if possible, as other immunosuppressive agents take effect over several weeks or months.

Evidence

There are no data comparing different oral CS regimens for the treatment of moderate lupus. Two controlled studies have shown that treating patients who are clinically stable but showing serological deterioration with a short course of moderate-dose CSs (e.g. 30 mg/day) can prevent more flares than placebo and lead to improvement in serological markers [46, 60]. However, there is a risk of treating patients that will not flare, and this approach is not recommended due to the side effects of CSs.

There are some data supporting the use of 100 mg i.v. MP pulses in non-renal lupus as an alternative to 1000 mg pulses [143], and for 1000 mg pulses on three occasions in patients with moderate or severe lupus, with very little oral prednisolone [146]. The data supporting the use of i.v. pulses of 500 or 1000 mg are discussed further below in the section on the management of severe lupus [148, 326]. There is one open-label RCT [142] comparing triamcinolone 100 mg given as an i.m. injection with a short course of oral MP tapered over 1 week. Overall, there was little difference between the regimens but some improvement was seen more quickly with the triamcinolone injection.

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

Conclusions

Overall the LOE for CSs by i.m. or i.v. injection in non-renal moderate lupus is 2+ and GOR is C.

AZA for moderate lupus (non-renal disease)

Summary

AZA is not licensed for the treatment of lupus, but has been used for over 40 years, and it is the most frequently used cytotoxic agent [327] in lupus. AZA treatment (1–2.5 mg/kg/day orally) has been associated with prevention of flares and a reduction in CS dosage (see below and Table 2). It is usually started in patients with moderate lupus activity (Table 7) in conjunction with CSs, as it can take up to 3 months to be effective. It is also used for maintenance therapy after remission or significant response has been achieved with other agents used to treat severe lupus (such as CYC) that are less suitable for long-term therapy, particularly in women desiring pregnancy, or who are pregnant or breast-feeding [24, 25, 239, 328]. Most of the evidence (and the only double-blind RCTs) supporting its use relate to the management of LN [24, 25]. Only papers discussing the management of non-renal lupus with AZA are discussed here, although in some cases the studies included renal and non-renal patients. There is no evidence that it prevents atherosclerosis or other forms of damage [12, 329].

Evidence

The first reports of AZA being used for renal and non-renal manifestations of lupus with CSs appeared in the late 1960s and 1970s [149–151, 153, 330, 331]. Reduction in disease activity and flare rate and steroid-sparing effects were demonstrated in most of these open-label, controlled studies and in a case series [158]. AZA 200 mg daily was associated with an increased risk of significant liver dysfunction. There was no increased risk of infection, even starting at 3–4 mg/kg/day, but subsequent studies have used 2–2.5 mg/kg/day.

A prospective longitudinal open-label study [154] involving 17 SLE patients showed that AZA reduced lupus activity and anti-dsDNA antibody levels. Subsequently, in a retrospective study [155] with 61 SLE patients, suppression of anti-dsDNA antibodies by AZA (2 mg/kg/day) and low-dose prednisolone (7–12 mg/day) was associated with efficacy and better long-term outcome. However, the presence of renal disease, persistence of anti-dsDNA antibodies for at least 1 year after the beginning of treatment and reduction in AZA dosage to below 2 mg/kg/day predicted flares and was associated with a higher rate of lupus-related death.

An open-label, multicentre, RCT study of 89 SLE patients requiring 15 mg or more of prednisolone compared AZA (mean dose 2.1 mg/kg/day) with ciclosporin (mean dose 2.2 mg/kg/day) for its steroid-sparing properties [152]. The absolute mean change in prednisolone dose at 12 months, adjusted for baseline prednisolone dose, was not significantly different: 9.0 mg for ciclosporin (95% CI: 7.2, 10.8) and 10.7 mg for AZA (95% CI: 8.8, 12.7). There was no difference between groups in change in disease activity or number of flares, development of new damage, change in quality of life or numbers of patients discontinuing study drugs due to adverse events or lack of efficacy [152]. The conclusion was that both drugs can be used in lupus for their steroid-sparing properties, with appropriate monitoring.

AZA is usually well tolerated [332]. The main adverse events are nausea and vomiting, diarrhoea, flu-like illness with fever, rash, leucopenia and hepatotoxicity [156, 157, 332–334]. Side effects can occur soon after starting AZA and may require drug withdrawal [156, 335]. Hepatic veno-occlusive disease is a rare adverse event, but autoimmune hepatitis can improve on AZA, so this is not a contra-indication to its use [157]. AZA is not excreted by the kidney, and it can be used in patients with renal impairment. Managing patients with lupus-related leucopenia with AZA can be difficult [332, 336]. The enzyme thiopurine S-methyltransferase (TPMT) catalyses the inactivation of AZA. It is worth testing patients for TPMT [334] before starting AZA, as the very low level phenotype (homozygous deficiency that occurs in 0.3% Caucasians) is associated with potentially life-threatening bone marrow toxicity; otherwise, weekly full blood counts are required as the dose is increased over several weeks [337, 338]. Those patients with intermediate TPMT levels due to a heterozygous state have an increased risk of leucopenia as well, and such testing does not remove the need for monitoring the effects of the drug on the full blood count [156, 332] and liver function according to national or local guidelines [337, 338].

AZA does not cause infertility and has not been found to be teratogenic in clinical practice, despite theoretical concerns [339, 340]; thus, it can be used in women planning conception and is compatible with pregnancy and breast-feeding [24, 98, 239]. It may reduce the response to some immunizations [341–344], but this is not a contra-indication to immunization except with live viruses [74, 292]. There is no evidence that AZA increases the risk of malignancy in lupus patients [301, 345], but it may increase the risk of cervical dysplasia [346].

Conclusions

Although the data for AZA in non-renal lupus are much weaker than the data supporting its use in LN (see below), there are four open-label RCTs, three prospective cohort studies, two retrospective cohort studies and one case series supporting the use of AZA for non-renal lupus: overall LOE 2+, GOR C.

MMF for moderate lupus (non-renal disease)

Summary

There are increasing data showing that MMF in combination with CSs reduces moderate and severe lupus disease activity, reduces renal and non-renal flares, is associated with CS-sparing properties and is tolerated well (see Tables 2 and 7 for suggested treatment strategies). However, there are no placebo-controlled double-blind RCTs specifically designed to assess the use of MMF in non-renal lupus. It is teratogenic and is contra-

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

indicated in women trying to conceive, or who are pregnant or breast-feeding.

Evidence

The first systematic review of MMF (2–3 g daily) in non-renal lupus was published by Mok in 2007 [170] and reviewed 20 papers in terms of the response of specific clinical features (up to 2006) and steroid-sparing properties. This systematic review included patients mostly refractory to other therapies who were treated with MMF in uncontrolled studies for arthritis, renal, haematological and cutaneous manifestations, and a few with neuropsychiatric manifestations, and also covered the use of MMF in prevention of flare in a small prospective study of patients with rising anti-dsDNA antibody levels [162–164, 347].

A later systematic review [133] with a literature search up to end of October 2011 provided further evidence that MMF treatment is associated with reductions in disease activity, flare rate and prednisone dose and included data from five cohort studies [162–166] and from the Aspreva Lupus Management Study (ALMS) trial in LN that specifically reported on non-renal lupus manifestations (see below) [159]. Further supporting evidence for MMF comes from a small case series [169] and a study [348] showing that mycophenolic acid (MPA) levels vary between patients and that higher trough levels were associated with less risk of disease flare. MPA levels were more closely associated with efficacy and safety than the dose of MMF. This test is available in some hospitals, but the target trough level of 3.5–4.5 mg/l was recommended to be tested in a controlled trial before being widely applied.

The beneficial effects of MMF on non-renal disease activity [159] were demonstrated in a 6-month open-label RCT (ALMS) that compared oral MMF (target dose 3 g/day, median exposure 2.6 g/day) with pulses of i.v. CYC (0.5–1.0 g/month) as induction treatment for biopsy-proven LN [349]. All patients received prednisone starting at 60 mg/day that was tapered to 10 mg/day. There was induction of remission in $>$80% of patients treated with MMF for active disease at baseline in mucocutaneous, musculoskeletal, cardiorespiratory and vasculitis systems in addition to renal response in 56% (the primary end point) [349]. There were no flares in the patients on MMF, and complement levels and titres of anti-dsDNA antibodies normalized. Very similar renal and non-renal responses were seen in those given CYC [159]. However, more Black and Hispanic patients responded to MMF than i.v. CYC, and further trials are required to assess the role of race, ethnicity and geographical region on treatment response [350].

In the maintenance phase of ALMS [160], 227 patients from the 6-month induction study who met the renal clinical response criteria were randomized again to MMF (2 g/day) or AZA (2 mg/kg/day) in a 36-month, double-blind, double-dummy, phase III RCT [160]. Prednisolone $\leqslant$10 mg/day or its equivalent was allowed and was taken by 90% of the MMF group ($n = 116$) and 87% of the AZA group ($n = 111$). Secondary end points included an analysis of non-renal severe flare. Severe non-renal flare rates did not differ between groups: 6.9% for the MMF group and 6.3% for the AZA group. There were no significant differences in the changes in anti-dsDNA antibodies or complement levels between groups. However, MMF was superior to AZA in various renal parameters related to maintaining a renal response and in preventing renal relapse in these LN patients, irrespective of which induction treatment had led to their initial response, race and geographical region [160]. Adverse events were common in both groups ($>$95%) (mostly minor infections and gastrointestinal disorders). Serious adverse events occurred in 24% of the MMF group and 33% of the AZA group ($P = 0.11$). The rate of withdrawal due to adverse events was lower with MMF than AZA (25% *vs* 40%, $P = 0.02$).

Another randomized open-label controlled trial [161], in Caucasians predominantly, compared MMF (mean 2 g/day) and AZA (mean 124 mg/day) for maintenance therapy over 36 months, starting at week 12 after induction with a short course of i.v. CYC (6 $\times$ 500 mg over 10 weeks) for the management of biopsy-proven proliferative LN. All patients initially received three i.v. pulses of MP and were tapered from 0.5 mg/kg/day prednisone down to 5 mg/day at week 52 and then tapered further and stopped if possible. Both regimens were well tolerated, and there was comparable improvement in renal end points and non-renal parameters, including disease activity indices and C3 levels in both groups. There were less renal flares and less haematological adverse events with MMF than AZA (though this was not statistically significant in this study).

Since the systematic review [133], further studies reporting reduction in disease activity included a retrospective review of patients treated with MMF that found a significant reduction in mean weekly steroid dosage (from about 12.5 to 3 mg/day prednisone) [167]. A single-centre retrospective cohort study [168] involving 135 patients with SLE (50% with renal disease) and 43 patients with systemic vasculitis treated with MMF reported good responses in 46% of patients, and the mean prednisolone dosage was significantly reduced from 22 to 8 mg/day at 12 months. These and other studies have shown that adverse events occur in up to 44% of patients over 5 years: mostly mild gastrointestinal intolerance and infections, with leucopenia and hospitalization rare. In one study most patients tolerated the drug well, with 73% of patients on the drug at 12 months, and there was no relationship between adverse events and dose (250 mg to 3 g daily) [351]. However, there have been increasing reports of teratogenicity, and it should be stopped at least 6 weeks before a planned pregnancy, and MMF should not be taken by women who are pregnant or breast-feeding [239].

Yahya *et al.* [172] reported on a small open-label prospective study of 14 non-renal lupus patients randomized to mycophenolate sodium (MS) or standard care and showed that MS treatment was safe and was associated with reduced disease activity. A randomized open-label

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

trial [171] of 40 patients with primary systemic vasculitis or SLE compared MMF (2000 mg/day) and enteric-coated MS (1440 mg/day). The composite primary end point was treatment failure and/or drug intolerance over 12 months. MS was anticipated to be tolerated better, but no difference in tolerance was observed. Although MS was associated with slightly better efficacy, this may have been due to imbalance in factors affecting remission and relapse, despite randomization with minimization. This study did not support the use of MS as a better tolerated and efficacious alternative to MMF for routine use, but MS could be considered in patients with gastrointestinal side effects from MMF.

Conclusions

The evidence that MMF reduces disease activity, lupus flare and has steroid-sparing properties in non-renal lupus comes from two systematic reviews, three open-label RCTs in LN and seven cohort studies: LOE 2++, GOR B. MPA/sodium (MS) may be considered in patients intolerant of MMF based on two studies (LOE three, GOR D).

Ciclosporin and tacrolimus for moderate lupus (non-renal disease)

Summary

Ciclosporin and tacrolimus do not cause myelosuppression and have the ability to reduce moderate disease activity (Tables 2 and 7). There is more evidence for ciclosporin in non-renal lupus, and it has been particularly helpful in the treatment of cytopenias, where there is likely to be difficulty distinguishing cytopenias due to lupus from cytopenias due to drugs such as AZA, MTX and MMF. Both ciclosporin and tacrolimus can be used (at the lowest possible dose) in women planning pregnancy, and in those who are pregnant or breast-feeding [239].

Evidence

There are two open-label RCTs [152, 173] and eight non-renal cohort studies supporting the use of ciclosporin at doses of $\leqslant$2.5 mg/kg/day in patients with normal renal function, although a systematic review [133] that included details of two open-label RCTs and a brief summary of six of the cohort studies reported that there was not much evidence supporting the use of ciclosporin in lupus because there were no double-blind, placebo-controlled RCTs.

Nevertheless, the open-label RCTs suggested that ciclosporin reduced disease activity as well as AZA did [152] and better than CSs alone [173], and that ciclosporin treatment was associated with significant CS-sparing properties in both RCTs, equivalent to that of AZA in one trial [152] as reported previously by the cohort studies. These included two prospective cohort studies [174, 175] that showed significant reduction in disease activity at 6 months, with most benefit in patients with renal and/or haematological manifestations, and response maintained to 24 months in one study [175]. Three retrospective studies [176–178] reported a reduction in disease activity and/or flares (particularly haematological manifestations such as thrombocytopenia), and significant steroid-sparing properties were reported in two of these studies [175, 177].

In the first of two additional studies not mentioned in the systematic review, ciclosporin was shown to treat thrombocytopenia in six patients [179], three of whom were able to stop CSs. In the second study [180], a retrospective cohort study, ciclosporin was used to manage 40 refractory lupus patients, including 11 patients with neurological conditions and 7 with overlap syndromes, as well as 18 with LN. The study showed reduction in disease activity and only mild transient adverse events not requiring discontinuation.

Adverse events were the focus of another study [181] with doses up to 5 mg/kg/day, so it was not surprising that adverse events were reported in 63%, but these led to discontinuation in only 16% and were reversible within 3 months of stopping the drug, consistent with many other reports. Ciclosporin treatment can cause hypertrichosis, gum hypertrophy, hypertension, paresthesiae, tremor, gastrointestinal symptoms and impaired renal function, especially at higher doses ($>$3 mg/kg/day). It is best used at lower doses ($\leqslant$2.5 mg/kg/day) as that is more tolerable and rarely causes permanent nephrotoxicity if carefully monitored. In the open-label RCT [152], there were no unexpected adverse events, and with appropriate monitoring of renal function and blood pressure, it was not discontinued due to adverse events or inefficacy more often than AZA.

There are two reports of tacrolimus in non-renal lupus and they were included in the systematic review [133]. The first was a small retrospective cohort study [182] with 10 non-renal patients showing significant reductions in SLEDAI and prednisolone over 1 year on 1–3 mg daily. The second was an open-label prospective study [183] with 21 mostly non-renal patients showing reduction in SLEDAI score over 6 months and no serious side effects, but 29% withdrew due to inefficacy and 10% due to adverse events.

Conclusions

Overall, the LOE for ciclosporin in non-renal lupus from two open-label RCTs, eight non-renal cohort studies and one systematic review is 2+ and GOR is C.

The LOE for tacrolimus from two studies in non-renal lupus and one systematic review is three and GOR is D.

LEF in moderate lupus

Summary

The systematic review [133] and our search found little evidence for efficacy and safety of LEF in lupus patients, with only two small studies in the literature. This drug can be considered in patients refractory to, not suitable for or intolerant of MTX, AZA, MMF and calcineurin inhibitors, for whom CYC, rituximab and belimumab are not suitable or not available. It is not suitable for women considering pregnancy, and a cholestyramine washout is required if pregnancy is desired or occurs while it is being taken [239].

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

Evidence

There was a randomized, double-blind, placebo-controlled trial in moderate SLE patients, with only six patients in each group [184]. A significant reduction in SLEDAI and prednisone occurred in both groups over 24 weeks. The LEF group showed significantly greater mean reduction in SLEDAI score, but there was no difference in steroid reduction between the groups. Side effects included transiently abnormal alanine aminotransferase (ALT), leucopenia and hypertension. There was a retrospective analysis of 18 patients who received LEF [185], but 4 patients withdrew (3 due to adverse events, including 1 with rash), and only 9/14 achieved lower SLEDAI scores after 2–3 months of therapy.

Conclusions

Overall the LOE for LEF for reducing non-renal lupus disease activity from two studies is three and the GOR is D. Caution is advised about its use in those with pre-existing subacute cutaneous lupus, as this may worsen as observed in other non-lupus studies.

Rituximab for refractory moderate lupus

Summary

Rituximab can be prescribed and reimbursed in the UK currently according to the NHS England 2013 Interim Clinical Commissioning Policy Statement for rituximab in adult SLE patients [267] who have two or more systems with BILAG B scores; or have severe BILAG A level disease activity, using the BILAG-2004 index [268, 269]; or have a SLEDAI-2 K score [270] >6 if they have failed two or more immunosuppressive agents (due to inefficacy or intolerance), at least one of which must be MMF or CYC; or need unacceptably high doses of steroids to achieve lower level of disease activity.

The patients must be managed in conjunction with a specialist centre for lupus and be entered in to the BILAG Biologics Register for standardized reporting of outcome (see Fig. 1 flowchart for eligibility and response criteria). This is essential for providing more open-label data in a prospective study with control patients treated with other immunosuppressive therapies, given the failure of the international double-blind, placebo-controlled lupus trials to meet their primary end points, as discussed below (EXPLORER for active non-renal disease [190, 191] and LUNAR for LN [352]). This policy was agreed as a result of the increasing published evidence supporting the efficacy of rituximab in refractory lupus patients, who are likely to differ from those recruited to trials where there was no requirement to have failed conventional therapy. Pregnancy should be avoided for at least 6 months after exposure to rituximab [239].

Evidence

The current evidence supporting the efficacy and safety of rituximab in non-renal lupus was most recently reported in a systematic review [200] in 2014 by Cobo-Ibanez with a literature search up to June 2013. This included the non-renal RCT EXPLORER [190] and its exploratory analysis [191], 2 open-label phase I/II trials [192, 193] and 22 cohort studies which analysed 1231 patients in total [200]. The 2 open-label trials [192, 193] and 5 of the cohort studies had been discussed in a previous systematic review summarizing off-label use in 188 cases (including non-renal and renal patients in 9 cohort studies and 26 case series/reports published up to December 2007) [202].

The non-renal patients discussed in the systematic review by Cobo-Ibáñez *et al.* [200] were heterogeneous, but in general had active lupus disease unresponsive to steroids and/or immunosuppressants prior to treatment with rituximab. Treatment with rituximab was associated with a reduction in global disease activity over 3–9 months, with 64–91% achieving response, including patients with a reduction in complement and anti-dsDNA antibody levels, arthritis and thrombocytopenia. Evidence for a steroid-sparing effect was based on the 2 open-label trials and 10 of the cohort studies [200]. There were few significant adverse events in the RCT, 2 open-label studies and 20 cohort studies [200]. Relapses/flares did occur at variable times (3.7–18 months), although in the RCT there were numerically fewer severe BILAG A flares and longer time to these flares in the rituximab group compared with the placebo group, and this almost achieved statistical significance (hazard ratio = 0.61, P = 0.052) [191]. Better clinical response after a second course was observed in 2 of the cohorts that studied retreatment [200], and a further report supported this observation and that steroid reduction occurred after each of two courses of rituximab [199]. The evidence for rituximab treating mucocutaneous involvement was deemed weak [200], and this may be explained by a recent report [353] specifically addressing 26 SLE patients with various subtypes of lupus rash, which observed that acute lupus rash responded whereas chronic cutaneous lupus (such as discoid rash) did not respond to rituximab and that new lesions with typical histology may appear despite confirmed B cell depletion.

Rituximab treatment early in the course of lupus disease, followed by AZA, was tried by Ezeonyeji *et al.* [194] specifically for its steroid-sparing effect in a pilot study with 8 SLE patients whose results were compared with 23 matched historical control patients treated conventionally [194]. Reduction in disease activity, a fall in anti-dsDNA antibodies and complement, and significant lower cumulative prednisolone at 6 months compared with controls was observed. There is also an open-label LN study suggesting that early rituximab with i.v. MP followed by MMF may avoid the use of oral CSs, and this regimen is currently being tested in a controlled randomized RCT called RITUXILUP [354].

The Duxbury systematic review and meta-analysis [201] reported response rates for various disease activity measures for patients in the open-label studies of refractory lupus treated with rituximab also reviewed by Cobo-Ibáñez *et al.* [200]. The Duxbury review and meta-analysis

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

did include a section on LN (not discussed here) and included a few non-renal studies not in the Cobo-Ibáñez review, although the latter also included a few not in the Duxbury review. The BILAG index was used in 188 patients treated with rituximab in 8 open-label studies (3 prospective, 4 retrospective and 1 small case–control) [201]. The pooled global response in seven of these studies was 83%. The complete response rate was 47% and the partial response rate was 38% in six studies. A significant reduction in anti-dsDNA antibodies was observed in 6 of the 8 studies and a significant rise in complement was observed in 5 of 6 studies. Various versions of the SLEDAI were used in 513 patients treated with rituximab in 12 open-label studies: 5 prospective, 6 retrospective and 1 open-label randomized trial, only 1 of which also analysed BILAG response. With SLEDAI the global response was 77% in 11 studies. In 6 studies the complete response rate was 57% and the partial response rate was 31%. Anti-dsDNA levels fell in 3 of 3 studies and complement rose in 2 of 3 studies [201].

Publications from cohorts in Germany [195], Italy [196] and Japan [197] have confirmed similar levels of efficacy with various disease activity measures and provided further safety data in another 264 patients. Long-term follow-up of 98 SLE patients treated with rituximab over a 12-year period has shown in a retrospective analysis that the group with longer duration of depletion ($\geqslant$12 months) was associated with a better response (greater decrease in BILAG score at 6 and 12 months) than those with shorter period of B cell depletion [198].

The results of these open-label studies are much better than the response rates observed in the EXPLORER RCT (for rituximab *vs* placebo: complete 12% *vs* 16%, partial 17% *vs* 13%) [190]. However, EXPLORER used more stringent BILAG response criteria than used in any other study [201], but did observe a reduced rate and time to severe BILAG A flare [191]. High-dose CSs and background immunosuppression were used in both arms of the EXPLORER trial and may have reduced the ability to discriminate benefit from rituximab [201]. Patients on MTX as the background immunosuppressant derived more benefit from rituximab in a *post hoc* analysis than those in the placebo group [190], and in contrast to those on background AZA or MMF [190]. Patients of Afro-American or Hispanic origin were also shown to benefit from rituximab in the RCT, in contrast to Caucasians [190].

However, two case series reports have suggested that repeat courses of rituximab may increase the risk of hypogammaglobulinaemia and infection [199, 293]. Progressive multifocal leukoencephalopathy (PML) has been reported in 17 SLE patients, of whom 5 had been treated with rituximab. It seems likely that immunosuppression, however it is achieved, is the key factor in the development of PML. Lupus patients may be at increased risk of developing PML compared with other rheumatic diseases [355]. The risk of rituximab causing PML in rheumatic diseases, including RA and SLE, has been estimated at 5/100 000, which is less than the risk observed with some other immunosuppressants in other diseases [356].

Conclusions

There is now considerable evidence for the ability of rituximab to reduce disease activity in refractory non-renal SLE of moderate and severe severity, albeit mostly from cohort studies. There have been relatively few concerns in the individual reports and systematic reviews about adverse events, including infections, in lupus patients on rituximab. There is increasing evidence that rituximab has steroid-sparing properties, but further evidence for its use early in the disease course is needed. Overall, the LOE for rituximab from 3 systematic reviews (including a meta-analysis and 30 studies, including 1 RCT and 3 open-label trials for reducing disease activity and for steroid-sparing properties) is 2+ and the GOR is C.

Belimumab for refractory moderate lupus

Summary

There have been two large phase III RCTs [203, 204] investigating the use of belimumab in moderate–severe seropositive lupus (mostly musculoskeletal and cutaneous disease; as severe active renal and NPSLE disease were exclusions). All patients received steroids, HCQ and/or immunosuppressive drugs, with specific criteria for dosing changes allowed or contra-indicated in the protocol. Both trials showed a significantly increased proportion of responders to belimumab at a 10 mg/kg dose in addition to standard care. A variety of secondary end points were met, and there were no significant differences in adverse events, leading to the drug being approved and licensed by the US Food and Drug Administration and the European Medicines Agency. NICE guidance for use of belimumab in active autoantibody-positive SLE in adults has been published [324] and is summarized in Fig. 1. Patients must have positive anti-dsDNA antibodies, low complement and a SELENA-SLEDAI score $\geqslant$10 despite standard therapy. Patients should be recruited to the BILAG Biologics Register so that outcomes can be recorded, and treatment with belimumab should not be continued for $>$24 weeks unless the SELENA-SLEDAI score has improved by 4 points or more. Pregnancy should not occur while on belimumab, but first trimester exposure is unlikely to be harmful [239].

Evidence

In the BLISS52 trial [203], at week 52 the response rate with placebo was 44%, with belimumab 1 mg/kg it was 51% ($P = 0.013$) and with 10 mg/kg it was 58% ($P = 0.001$). In the BLISS76 trial [204], the placebo response rate at week 52 was 34%, with belimumab 1 mg/kg it was 41% ($P = 0.089$) and with 10 mg/kg it was 43% ($P = 0.017$). The response rates at week 76 were a little lower in all groups. A meta-analysis of the response at 52 weeks in the phase II trial of belimumab [205] as well as BLISS 52 and BLISS 76 trials showed benefit for belimumab, with an odds ratio of 1.63 (95% CI: 1.27, 2.09) [209]. Safety data from the phase II trial and its open-label extension have not shown any significant concerns and continued benefit for up to 7 years [207, 208]. The most common side effects have been upper respiratory tract and urinary tract infections,

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

arthralgia, headaches, fatigue and nausea. Serious infusion reactions and infections have been rare [207, 208]. There have been two case reports of progressive multifocal leukoencephalopathy [357, 358], but there is no evidence that belimumab increases the risk more than other immunosuppressive regimens in SLE patients [356].

Further *post hoc* analyses [359, 360] on the pooled datasets from BLISS 52 and BLISS 76 trials have demonstrated that belimumab therapy was associated with significantly more patients showing improvements than with placebo in the most commonly affected musculoskeletal and mucocutaneous systems, and more immunological abnormalities normalized than with placebo [359]. Improvement was reported less consistently in other systems that were less often affected [359]. There was less worsening in haematological, immunological and renal parameters in those patients on belimumab than in those on placebo [359], but as with improvement, effects were not always dose related. Serological improvements (reduction in anti-dsDNA antibodies and increase in C3/C4 levels, without reduction in memory T or B cell numbers or levels of anti-pneumococcal or anti-tetanus toxoid antibodies) have been reported [361]. This is consistent with the low rate of serious infections in the long-term open-label study of belimumab [207, 208].

Another pooled analysis of BLISS 52 and BLISS 76 trials identified that belimumab had most therapeutic benefit compared with standard therapy alone in patients with higher disease activity (SELENA-SLEDAI $\geqslant$10), positive anti-dsDNA antibodies, low complement, or CS treatment at baseline [206]. Week 52 response rates in the low complement/anti-dsDNA–positive subgroup were 32% for placebo, 42% for belimumab 1 mg/kg ($P = 0.002$) and 52% for belimumab 10 mg/kg groups ($P < 0.001$). For the SELENA-SLEDAI $\geqslant$10 subgroup, the response rates were 44%, 58% ($P < 0.001$) and 63% ($P < 0.001$), respectively. Belimumab was also shown to reduce severe flares and CS use and to improve health-related quality of life most in these more severe subgroups [206]. These analyses contributed to the decision by the European Medicines Agency to limit the market authorization for belimumab (Benlysta) to add-on therapy in adult patients with active autoantibody-positive SLE with a high degree of disease activity (e.g. positive anti-dsDNA and low complement) despite standard therapy [362].

Conclusions

Treatment with belimumab in addition to standard therapy in autoantibody-positive SLE patients was associated with some improvements in clinical, laboratory and patient-reported outcome measures (compared with placebo in addition to standard therapy) and had a low risk of serious side effects. Based on the results of the two RCTs and the *post hoc* analyses, belimumab is considered by NICE to be cost-effective in the UK only for patients who meet the specific criteria [324] (see summary above and Fig. 1), so availability is limited. The drug is being used in other countries, particularly in the USA, where the licence covers patients with moderate disease activity and only specifies that patients must have active, autoantibody-positive lupus and be receiving standard therapy (such as CSs, antimalarials, immunosuppressives and NSAIDs) [363]. Overall, the LOE for belimumab in non-renal lupus from a meta-analysis, one phase II study, two phase III RCTs, their open-label extension study and *post hoc* analyses combining the data from the two RCTs is 1+ and the GOR is B.

Recommendations for the management of severe SLE

(i) Patients who present with severe SLE, including renal and NP manifestations, need thorough investigation to exclude other aetiologies, including infection (4/D). Treatment is dependent on the underlying aetiology (inflammatory and/or thrombotic), and patients should be treated accordingly with immunosuppression and/or anticoagulation, respectively (4/D) (SOA 98%).

(ii) Immunosuppressive regimens for severe active SLE involve i.v. MP (2+/C) or high-dose oral prednisolone (up to 1 mg/kg/day) (4/D) to induce remission, either on their own or more often as part of a treatment protocol with another immunosuppressive drug (4/D) (SOA 98%).

(iii) MMF or CYC are used for most cases of LN and for refractory, severe non-renal disease (2 ++/B) (SOA 98%).

(iv) Biologic therapies belimumab (1+/B) or rituximab (2+/C) may be considered, on a case-by-case basis, where patients have failed to respond to other immunosuppressive drugs, due to inefficacy or intolerance (SOA 98%).

(v) IVIG (2−/D) and plasmapheresis (3/D) may be considered in patients with refractory cytopaenias, thrombotic thrombocytopaenic purpura (TTP) (1+/B), rapidly deteriorating acute confusional state and the catastrophic variant of APS (SOA 93%).

Rationale

Overview of the management of severe lupus

Patients who have serious manifestations with organ- or life-threatening disease require treatment with intensive immunosuppression followed by a prolonged period of less aggressive maintenance therapy to prevent relapse (summarized with suggested dosing regimens in Table 7). In some cases there may be a thrombotic component to the clinical features that requires anticoagulation, for example in patients with APS as well as lupus. There is most evidence for the management of LN, less for neuropsychiatric disease and very little for other organ-specific manifestations.

The authors of this guideline have not reviewed the evidence for the management of LN as they suggest that the EULAR/ERA-EDTA recommendations for the management of adult and paediatric LN [24] are followed. The main recommendations and SOAs with them are shown in Table 3. Further details about these recommendations and the evidence for them have been published [24].

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

For the management of severe non-renal SLE, the evidence for treatment with high-dose CSs, AZA, CYC, MMF, rituximab, IVIG and plasma exchange (plasmapheresis) is discussed below. The evidence for use of belimumab and of the calcineurin inhibitors ciclosporin and tacrolimus, particularly for cytopenias due to lupus, has already been reviewed above. Suggested initial target dosing regimens and lower maintenance regimens to prevent flares once patients are stable are shown in Table 7. The actual regimen used for individual patients will depend on the clinical picture and the treatment history. Patients with refractory disease, especially those being considered for belimumab and rituximab, should be discussed with and/or seen by a specialist lupus centre (see Fig. 1 flowchart for eligibility and response criteria). It is important to review the response regularly and to increase the dose and/or change the treatment if patients fail to respond.

CSs for severe SLE

Summary

The emphasis in the last 10 years has been on finding steroid-sparing regimens to treat severe lupus, using other immunosuppressants in conjunction with CSs (either orally, intravenously or both), to induce and maintain response with the least risk of adverse events, particularly infection. In general, there is an increasing tendency to use oral prednisolone at a dose of 0.5 mg/kg/day with i.v. MP pulses (3 $\times$ 500–750 mg) rather than higher doses of i.v. MP pulses and/or higher dose of oral prednisolone (e.g. 0.75–1 mg/kg/day) as done in the past for all severe manifestations of lupus.

Evidence

I.v. MP pulses as an alternative to, or in addition to, high-dose oral prednisolone was first reported as a treatment for LN [24, 325, 326]. I.v. MP pulses were introduced for the management of non-renal lupus in the early 1980s [147]. An open-label cohort study [146] and an open-label trial [145] using i.v. MP pulses followed by alternate day oral CSs found that pulse therapy led to rapid improvement in clinical symptoms and anti-dsDNA and C3 levels, but that an alternate day oral regimen was associated with relapses. A small double-blind, placebo-controlled RCT with mostly non-renal SLE patients [144] found that 3 i.v. MP pulses resulted in faster and more complete improvement in the first 2 weeks in 12 patients with SLE, but there was no significant difference in efficacy or safety parameters at 4 weeks or 6 months compared with the placebo group; however, all patients received 40–60 mg of oral prednisolone daily [144].

A double-blind RCT [143] comparing three daily i.v. MP pulses of either 1000 or 100 mg in 21 patients with SLE causing fever, cardiorespiratory, renal or NP manifestations (with individualized outcomes based on entry manifestations) suggested no difference in efficacy between the regimens. A retrospective study compared low-dose i.v. MP pulses ($\leqslant$1500 mg over 3 days) with high-dose pulses (3–5 g over 3–5 days) for the treatment of severe flares [148]. This study suggested that the lower dose was sufficient and safer for controlling SLE flares than the high-dose regimen, which was associated with an increased number of infections [148].

Conclusions

There is limited evidence for any particular CS regimen for specific manifestations of severe non-renal lupus. Overall the LOE for i.v. MP pulses and oral prednisolone in non-renal severe lupus is 2+ and the GOR is C.

AZA in severe SLE

Summary

AZA (2–3 mg/kg/day) is sometimes used as first-line therapy with CSs in severe non-renal lupus (see Table 7), based on the evidence discussed in the section on the use of AZA for the management of moderate lupus. It is most often used in women planning pregnancy or pregnant, as it is much safer in pregnancy than CYC or MMF, which are contra-indicated in such situations [239].

Evidence

There was only one open-label controlled trial, with 24 patients with severe (life-threatening) multisystem manifestations of lupus [151], which showed no definite benefit from the addition of AZA compared with 40–60 mg prednisone alone for 6 months, before tapering over the next 18 months, although there was some steroid-sparing benefits seen at 12 months. It has been used as primary treatment at a dose of 2 mg/kg/day as an alternative to MMF or CYC in low-risk renal patients without adverse prognostic factors and when these drugs are contra-indicated, not tolerated or unavailable [24].

AZA has been used more often as maintenance therapy after a course of CYC for severe lupus, based on the evidence from studies undertaken in patients with LN [24, 25]. The rate of major extra-renal flares in the maintenance phase of the Aspreva Lupus Management Study (ALMS) study was low in the AZA group at 6.3% (7/111) and similar to the frequency of 6.9% (8/116) in the MMF group [160]. There is some evidence that AZA may be less effective at preventing renal flare in patients in this LN study than MMF, as discussed in the section on MMF [160]. However in a predominantly Caucasian LN population, in the MAINTAIN study, no difference in number or time of severe systemic flares in the AZA group (4/43) compared with the MMF group (3/53) was observed [161]. There are no trials or controlled studies addressing AZA as a primary treatment for neuropsychiatric lupus or any other specific serious non-renal manifestations of lupus, but it has been used after CYC for the treatment and prevention of recurrence of lupus psychosis in 13 patients [328].

The systematic review of non-biologic immunosuppressants in non-renal SLE by Pego-Reigosa *et al.* [133] only considered the unblinded RCT (showing no benefit) from 1975 [151] and a cohort study (showing a reduced rate of flare [155] in patients on AZA) and concluded that there was little evidence to support the use of AZA in non-renal lupus.

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

Conclusions

Overall, the LOE for AZA in non-renal severe lupus is 2+ and the GOR is C.

CYC in severe SLE including LN and neuropsychiatric lupus

Summary

CYC, although not licensed for lupus, has been used for the treatment of severe lupus, particularly LN and organ- or life-threatening non-renal disease, since the late 1960s, with the first open-label trial in LN reported in 1971 [364]. Oral CYC is associated with an increased risk of bladder cancer and has been replaced by i.v. CYC pulses in the management of severe lupus. There is most experience with i.v. CYC pulses in LN and NPSLE (Tables 3 and 7). CYC is teratogenic and is contra-indicated in women trying to conceive, or who are pregnant or breast-feeding. It is gonadotoxic and can cause infertility, and men should not father children while on CYC [239].

Evidence

The first controlled trial comparing prednisone with CYC in LN, non-renal lupus and PM was reported in 1973 [365], and a similar design was used to compare oral CYC and AZA in lupus not responsive to 15 mg prednisolone [366], but numbers were small and the aim of matching individual patients and comparing their outcomes was unsuccessful. Since then, studies have used different trial designs and evidence supporting the use of various doses of oral and later i.v. pulse CYC regimens to reduce disease activity and prednisolone dosage and to improve outcomes in patients with LN and non-renal lupus have been reported. The best-known regimens are based on the National Institutes for Health i.v. CYC protocol (monthly i.v. CYC at 500–1000 mg/m^2 body surface area for 6 months, followed by 3 monthly i.v. CYC for 2 years) [367] and the Euro-Lupus protocol, which uses lower doses (500 mg fixed dose i.v. CYC 2-weekly for a total of 6 doses, followed by oral AZA) [368] and appears to be as effective and safer for LN in Europe than high-dose regimens [369]. In recent years, the 3-monthly i.v. CYC maintenance pulses for 2 years in the National Institutes for Health protocol have been replaced by oral MMF or AZA [25, 370].

I.v. CYC pulses were the most widely used regimes for all but the mildest cases of acute proliferative glomerulonephritis until MMF was found to be comparable in efficacy and safer [24, 25]. It should be noted that neither of these drugs is licensed for the treatment of LN, but both are supported as appropriate treatment for the management of LN in the EULAR/ERA-EDTA recommendations for the management of adult and paediatric LN [24] (Table 3) and the ACR guidelines for screening, treatment and management of LN [25].

Treatment regimens tested in LN have often been applied to severe non-renal lupus disease as there are fewer non-renal studies and they include heterogeneous patient populations. A systematic review [133] evaluated 29 studies, including 4 unblinded RCTs in which 3742 patients with non-renal lupus were treated with a variety of CYC regimens. There are more data on the efficacy and safety of using CYC to treat non-renal lupus than of any other drug treatment; however, there are fewer high-quality studies than for LN, and diverse end points have been used, making it hard to compare the studies.

Data from the ALMS RCT comparing i.v. CYC (0.5–1.0 g/m^2 monthly $\times$ 6) and MMF (target 3.0 g/day) as induction therapy for LN [159] showed that i.v. CYC therapy was associated with almost 95% response in all of the non-renal systems, apart from the haematology, which was confounded by drug-induced cytopenias and anaemia of uncertain cause. There was no difference in response between i.v. CYC or MMF in any of the systems studied, including renal.

Some of the best evidence supports the use of pulse i.v. CYC in NP lupus, with one small RCT favouring an i.v. CYC regimen over i.v. MP alone [186]. That trial used more CSs than we would recommend now and was based on a previous retrospective cohort study that suggested that i.v. CYC was useful in the management of NPSLE [371]. The RCT [186] recruited 32 SLE patients with active severe NP manifestations without thrombosis (such as seizures, optic neuritis, peripheral or cranial neuropathy, coma, brainstem disease or transverse myelitis) that had developed within the previous 15 days. All of the patients received oral prednisolone 1mg/kg/day for up to 3 months and then tapered depending on response and 1 g of i.v. MP daily for 3 days. One group received further 1 g of i.v. MP daily for 3 days repeated monthly for 4 months then bimonthly for 6 months and finally 3 monthly for one year. The other group received i.v. CYC 0.75g/m^2 body surface monthly for 12 months then this dose was repeated every 3 months for another year. The primary end point was at least 20% improvement from baseline using clinical, laboratory or specific neurological criteria and was met in 18/19 (95%) receiving CYC and 6/13 (46%) receiving MP [186]. A Cochrane systematic review of the treatment of NPSLE [372] calculated a relative risk of 2.05 (95% CI: 1.13, 3.73) for 20% response at 24 months with CYC therapy, but most patients responded by 5 months. CYC treatment was also associated with greater improvement in other lupus manifestations, a significant reduction in SLEDAI score at 6 and 12 months, greater reduction in prednisolone dosage and more patients completing the protocol compared with the MP group. There was no difference in adverse events, including infections and deaths. Recruitment to the study was stopped early due to the higher failure rate of the MP arm. Although the RCT is not of high quality [372] due to the small number of patients studied, the heterogeneity of the NP events, the variable outcome measures used for their assessment, and potential confounding by variable oral CS dosing, it is clear that the i.v. MP regimen was not sufficient and that CYC was better at controlling active NPSLE and preventing relapse.

Further evidence for the use of CYC in NPSLE comes from a previous open-label, controlled pilot study on the

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

use of low-dose i.v. CYC, with a mean dose of 21 mg/day oral prednisone in 37 NPSLE patients, compared with oral prednisone alone in 23 patients (mean dose 21 mg/day) [187], and a cohort study [373] in which a low-dose regimen of i.v. CYC was used in 25 patients with NPSLE with benefit and a low risk of adverse events. A case series [328] found that treating 13 patients with lupus psychosis with oral prednisolone starting at 1 mg/kg/day for 8 weeks and oral CYC (1–2 mg/kg/day) for 6 months followed by oral AZA (1–2 mg/kg/day) led to improvement within a mean of 44 days and only one relapse with psychosis after 2 years; however, 23% developed other NP features and 38% had non-NP flares over the mean follow-up of 7 years. Anti-psychotic agents were used in nine patients for a mean of 6 months. Evidence for CYC and other treatments in neuro-ophthalmic manifestations of lupus have been reviewed in a systematic review [374], but the data on treatment is mostly based on case reports and small case series, for example cases with neuromyelitis optica treated with or without CYC [374].

In contrast to the studies assessing low-dose regimens, high-dose CYC has been studied as well in the hope of achieving better responses in severe lupus. An open-label, uncontrolled study [375] reported the initial safety and efficacy of high-dose CYC (50 mg/kg $\times$ 4 days) without stem cell transplantation in 14 patients with refractory moderate to severe SLE despite CSs and at least one immunosuppressant. A prospective RCT [188] was designed to compare the efficacy and safety of a widely used standard i.v. CYC regimen (monthly i.v. CYC at 750 mg/m^2 body surface area for 6 months, followed by 3 monthly i.v. CYC for 2 years) with this high-dose i.v. CYC regimen. Entry criteria included moderate-to-severe lupus with renal (22 patients), neurologic (14 patients) or other organ system involvement (11 patients). There was no evidence that response differed between the regimens, but non-responders to monthly i.v. CYC could be rescued with high-dose i.v. CYC. There was no difference in serious adverse events, infections, premature ovarian failure or deaths between the two groups. Leuprolide (a gonadotropin-releasing hormone analogue) was not used to protect against ovarian failure [376]. This should be considered with i.v. CYC moderate- and high-dose regimens [188], as amenorrhoea and ovarian failure are dose- and age-related adverse events of CYC [370, 377], but are rare with the European low-dose i.v. CYC regimen (500 mg 2-weekly for 3 months only) recommended for LN [24].

The remaining data [133] supporting the use of CYC for other serious non-renal manifestations of lupus are obtained predominantly from a variety of cohort studies, small case series and case reports, including 5 patients with systemic lupus vasculitis [378], 11 patients with myocarditis [379] and 5 patients with heart failure due to myocarditis [380]. There is one open-label RCT comparing i.v. CYC with enalapril for 6 months in the treatment of pulmonary hypertension, which showed greater benefit from CYC but an increased risk of infection and gastrointestinal side effects [189].

Conclusions

There is considerable evidence supporting the use of i.v. CYC to reduce disease activity and CS usage in severe lupus, for both renal and non-renal disease, including NPSLE. There is no evidence that CYC prevents chronic damage, and all regimens are teratogenic, but there is less risk with the Euro-Lupus regimen of adverse events (such gastrointestinal side effects, alopecia, infection, amenorrhoea and infertility due to ovarian failure) than with higher dose regimens [12, 16, 24, 25, 133, 372]. Overall, the LOE for the use of CYC in non-renal severe lupus, including NPSLE, from 1 systematic review including 29 studies and 1 systematic Cochrane review of NPSLE is 2++, and the GOR is B.

MMF in severe SLE

Summary

There is considerable evidence supporting the use of MMF in the management of LN, and this has been discussed in the Joint EULAR/ERA-EDTA recommendations for the management of adult and paediatric LN [24] (Table 3) and the ACR guidelines for screening, treatment and management of LN [25]. The mean SOA of all of the authors of this guideline with each of the main EULAR/ERA-EDTA recommendations for the management of LN is shown in Table 3. There is very little evidence for the use of MMF in NPSLE, but it is being used to reduce other types of moderate and severe non-renal lupus disease activity (Table 7), to prevent flare and for its steroid-sparing properties, as an alternative to CYC or AZA, especially in cases where inefficacy, drug intolerance and concerns about toxicity arose. It is not compatible with conception, pregnancy or breast-feeding [239].

Evidence

As mentioned in the section on moderate lupus, there is a systematic review of non-biologic immunosuppressants in non-renal SLE [133] that summarizes the data from 8 papers (covering 768 patients with moderate/severe lupus), which assessed the efficacy and safety of MMF in the treatment of non-renal SLE, including the ALMS RCT comparing the use of MMF with that of CYC as induction therapy for LN [159], and 7 cohort studies including 6 discussed above [162–166, 351] and an abstract that does not meet the criteria for this guideline.

Conclusions

Overall, the LOE for MMF in non-renal lupus from 2 systematic reviews, 2 open-label RCTs in LN and 7 cohort studies is 2++, and the GOR is B.

Rituximab in severe SLE

Summary

According to the NHS England Interim Commissioning Policy Statement for rituximab in SLE [267], rituximab may be considered in patients with severe or moderate SLE (BILAG system category A or $\geqslant$2B system scores, or SLEDAI $>$6) who fail treatment with MMF or CYC, either because of lack of effect or due to adverse events,

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

providing they have already failed another immunosuppressant or it would be contra-indicated, or who require unacceptably high long-term CS dosing to control their lupus activity (see Fig. 1 flowchart for eligibility and response criteria).

Evidence

Clinical examples of severe lupus are shown in Table 7, and the evidence for rituximab is summarized in Table 2. The systematic reviews by Duxbury *et al.* [201] and Cobo-Ibáñez *et al.* [200] provide evidence supporting the use of rituximab for non-renal severe manifestations of lupus, such as NP involvement (5 cohort studies [381–385]), haematological manifestations (6 cohort studies [383, 385–389]) and at least 10 other cohort studies [382, 383, 385, 387, 390–395]). The data for improvement in NPSLE are still limited and uncontrolled, but showed 73–100% response in small numbers of patients. There is some evidence for improvement (50–100%) in mostly refractory lupus patients and idiopathic autoimmune thrombocytopenia and haemolytic anaemia. There are some specific reports on the use of rituximab in neuro-ophthalmological cases in a systematic review of these conditions [374], and pooled data from European cohorts [396] on the effects of rituximab in LN, as mentioned in the EULAR/ERA-EDTA recommendations for the management of adult and paediatric LN [24]. There are insufficient data to comment on other specific severe lupus manifestations at present, but rituximab is accepted as having steroid-sparing properties (three open-label studies [192, 193, 199]).

Conclusions

Overall, the LOE for rituximab from 3 systematic reviews and 30 studies, including 1RCT and 3 open-label trials for reducing lupus disease activity and for steroid-sparing properties, is 2+, and the GOR is C.

IVIG in severe SLE

Summary

IVIG has been used most in patients with refractory cytopaenias, thrombotic TTP and the catastrophic variant of APS. It can be used in pregnancy (but does not prevent heart block or fetal loss) and in patients with infection. It is rarely indicated as there is not much evidence for its use (Table 2).

Evidence

Much of the initial data are from case reports or small case series reporting treatment of acute events in small numbers of patients [223–226]. A systematic review and meta-analysis covering 3 controlled and 10 observational studies in SLE concluded that IVIG led to a reduction in SLE disease activity scores and a rise in complement levels in 31% of patients ($P = 0.001$, 95% CI: 22.1, 41.3) . There were insufficient data to assess response using other outcome measures, although serious adverse events were rare and mild [227]. The observational studies often did not report concomitant medication and used a variety of outcome measures and treatment regimens, as discussed below.

IVIG at a dose of 400 mg/kg/day for 5 consecutive days was used monthly for 6–24 months with some benefit in an open-label, uncontrolled trial with 12 refractory SLE patients [210]. Another open-label study [213] assessed 13 female SLE patients with a flare who received 0.4 g/kg body weight IVIG daily for 5 days. Short-term benefit was seen irrespective of concomitant therapy. IVIG–related adverse effects were mild and rare, and there was no worsening of renal function [213].

Low-dose IVIG was used to treat histologically confirmed cutaneous lupus in 12 patients starting with doses of 1 g/kg $\times$ 2, followed by 400 mg/kg monthly until disease remission or for 6 months [214]. Five patients showed complete or almost complete (>75%) clearing of their skin lesions, two had partial improvement (>50%) and three had poor responses (<50%). There were few side effects in this study, but renal patients were avoided because nephrotoxicity has been reported in other studies [397].

A retrospective chart review of 62 patients treated with low-dose IVIG (~0.5 g/kg) on average every 5 weeks for a mean of 6 courses showed a steady reduction in SLEDAI score over 8 months [215]. Patients with fever, rash, mucosal ulcers, pleurisy, pericarditis, urinary casts and urinary red cells responded in over 50% of cases, but only 30% of arthritis cases responded. Patients with thrombocytopenia, vasculitis and alopecia did not respond. Another group also found a disappointing response to IVIG in thrombocytopenia [216] in a retrospective analysis of 59 patients with immune-mediated severe thrombocytopenia, 44 of whom had definite lupus. A transient response to IVIG was reported in three patients with haemolytic anaemia in another study [217].

The effect of high-dose IVIG (30 g of sulfonated IVIG on days 1–4 and 21–24) in 12 mild to moderate active lupus patients [218] was only temporary in most patients. High-dose IVIG treatment in 17/20 (85%) SLE patients given 1–8 treatment courses consisting of 2 g/kg monthly given over 5 days [219] led to some improvement in arthritis, fever, thrombocytopenia and NP lupus [219]. A retrospective chart review of 17 patients (including 11 with SLE), with a mean follow-up of 30 months and long-term high-dose IVIG treatment monthly for 6 months then every 2–3 months [220], found that there was a significant reduction in the SLEDAI score with significant steroid-sparing effects, and remission was achieved in 12 patients [220].

A case–control study [221] compared 12 pregnant SLE patients with a history of recurrent spontaneous abortions who were on high-dose IVIG (0.5 g/kg every 3–33 weeks) with 12 similar patients treated with prednisolone and NSAIDs. Patients in the IVIG group stopped prednisolone ($n = 4$) and NSAIDs ($n = 9$). Disease activity decreased by the end of pregnancy ($P < 0.0001$) and there was a reduction in autoantibodies and normalization of complement levels in the IVIG group. Such improvements were not seen in the control group, and there were three fetal losses due to spontaneous abortion in this group compared with none in the IVIG group. However, other studies

Downloaded from https://academic.oup.com/rheumatology/article/57/1/e1/4318863 by guest on 03 February 2023

have not confirmed that IVIG can prevent fetal loss [239], and it is possible that NSAIDs contributed to fetal loss in the control group [240].

A multicentre, prospective, open-label study of pregnant women with anti-SSA/Ro antibodies in the mother and birth of a previous child with CHB/neonatal lupus rash was undertaken to determine whether IVIG (400 mg/kg) given every 3 weeks from weeks 12 to 24 of gestation could prevent the development of CHB [211]. CHB was detected at 19, 20 and 25 weeks in 3 babies at a stage when 20 mothers had completed the IVIG protocol before the trial was stopped. An additional child without CHB developed a transient rash consistent with neonatal lupus [211]. Another European prospective study showed similar results [212].

A large retrospective, single-centre cohort study was published by Camara in 2014 [222], which included 52 SLE patients with predominantly cutaneous, haematological, NP and cardiac manifestations who received at least one cycle of IVIG (400 mg/kg/day for 5 days). IVIG was given to 27 patients with infection and active lupus disease, and 17 (63%) patients showed some response. In 18 (69%) of 26 patients with refractory active disease without infection, some response was seen also. This study was too recent to be included in the comprehensive review on the use of IVIG in rheumatic diseases [228] that covered the case–control study in pregnancy by Perricone *et al.* [221], 4 prospective open-label studies [210, 213, 215, 218, 219], a retrospective cohort study [220] in lupus and a small RCT in LN not discussed here [228].

Conclusions

IVIG, particularly the high-dose regimen, can have some beneficial effects in the short term on disease activity, but has to be continued with intermittent courses for sustained benefit to be seen and only then has steroid-sparing properties. It has a low rate of adverse events in non-renal patients, but can cause nephrotoxicity, especially with pre-existing renal disease. The evidence supporting its use is weak compared with that of other treatments that are cheaper and easier to administer, so it should be reserved for patients in whom other treatments are contra-indicated or have failed. Overall, the LOE for IVIG in non-renal severe lupus from 2 systematic reviews (including a meta-analysis, 3 open-label trials, 10 cohort studies and 4 case series) is 2–, and the GOR is D.

Plasma exchange (plasmapharesis) for severe SLE

Summary

Plasma exchange in SLE has been used in small numbers of patients with conflicting results since the late 1970s. A systematic review was published while this paper was in preparation [238]. It is rarely indicated, because there is inadequate data to support its use except in thrombotic TTP (Table 2).

Evidence

The evidence supporting treatment with plasma exchange, which is expensive and often difficult to organize, remains poor except for thrombotic TTP [229, 398], the catastrophic variant of APS [238] and refractory neuropsychiatric, haematological and renal lupus [238]. Even for rapidly progressive glomerulonephritis, the evidence is limited [399].

Studies have shown that plasmapheresis can reduce immune complexes and anti-dsDNA antibodies, but there is a rapid rebound of complexes and antibodies to pre-treatment levels, as shown originally in 5/8 patients [230]. Marked improvement after plasma exchange was seen in 7/11 (64%) SLE patients in another study [231] lasting up to 3 years, but one (9%) patient with a severe relapse died, and plasma exchange was ineffective in 3 (27%) patients. In another small study of nine patients, 5 (56%) improved, 2 (22%) progressed to end-stage renal failure, and 2 (22%) died due to complications of severe SLE [232].

There was less support for the use of plasma exchange in SLE after a trial comparing plasma exchange in combination with CYC and CSs with standard therapy revealed no benefit from the plasma exchange for 40 patients with severe LN [400]. However, to avoid the rebound increase in autoantibodies after plasma exchange, a synchronized protocol was developed by the Lupus Plasmapharesis Study Group, consisting of plasmapheresis (3 $\times$ 60 ml/kg) followed by high-dose pulse CYC (36 mg/kg) then 6 months of oral immunosuppression. This treatment led to rapid improvement in disease activity in the initial 14 patients with various severe SLE manifestations, sufficient for immunosuppressants including CSs to be withdrawn in 12 (86%) patients at 6 months. Treatment-free clinical remission was sustained in 8 (57%) patients for a mean of 5.6 years [233]. However, there has been concern that improvements seen in this and 2 other uncontrolled studies [234, 235] with 23 patients may have been due to the concomitant immunosuppressants. It is notable that the Lupus Plasmapharesis Study Group never reported on the final disappointing results of a randomized international multicentre trial comparing their synchronized protocol [233] with the administration of pulse CYC alone.

The evidence for treating patients who have diffuse alveolar haemorrhage, thrombotic TTP or catastrophic APS with lupus is predominantly from case reports and small case series [229, 236, 237]. Given the high mortality in TTP in general, but especially with lupus [229, 398], it is essential that patients with TTP are referred early for plasma exchange and specialist care [398, 401]. Further details about the experience with and potential use of plasma exchange and immunoadsorption in lupus and APS, including LN, are covered by the systematic review [238].

Conclusions

There remains a need for further research to better define the patients who are most likely to benefit from plasma exchange, but in general they are considered to be those who have TTP, severe refractory disease or contra-indications to conventional treatment (such as pregnancy). Overall, the LOE for plasma exchange for the treatment of non-renal severe lupus from one systematic review and

Table 8 Research priorities to improve the management of lupus patients

Analysis of the BILAG Biologics Register data is needed to assess the efficacy and safety of using rituximab for treating refractory lupus disease, administered according to the NHS England Interim Clinical Commissioning Policy Statement.
Analysis of the BILAG Biologics Register should also provide some data on the use of MMF in non-renal lupus patients; this is needed to support data from previous renal trials.
More research into stratified and personalised medicine and the cost-effectiveness of immunosuppressive drugs in lupus patients is warranted to help identify which drug will be most suitable for an individual.
Trials of immunosuppressive regimens and biologic therapies that will significantly reduce the need for CSs are needed in renal and non-renal lupus patients.
The cost-effectiveness and value of monitoring drug levels in order to improve adherence/compliance with drug therapy and improve the outcome in terms of reduced disease activity, damage and steroid usage should be investigated (e.g. for HCQ, MMF).
The role of IVIG and plasma exchange in the management of lupus patients requires further evaluation.
More data are required on the long-term outcome for children born to mothers with lupus who were exposed to drugs used pre-conception, while pregnant and/or while breast-feeding.

NHS: National Health Service.

nine studies is weak [3], and the GOR is D, but for TTP it is strongly recommended (grade B), as for non-lupus patients with TTP.

Applicability and utility

Implementation

Diagnosis and assessment of lupus can be difficult due to multisystem involvement and variable laboratory and serological test results. These guidelines will increase knowledge and raise the standard of care for patients with lupus. Only HCQ, CSs and belimumab are licensed treatments for lupus. The evidence for the treatment options discussed in this guideline, which reflect current best practice, has increased considerably in the last 10 years, although there is still relatively little evidence from high-quality RCTs. There should be no barriers to implementation, apart from limitations on the funding for rituximab and belimumab discussed in the relevant sections. The guidelines will be widely presented at local, regional and national meetings for health professionals and patients, carers and supporters of relevant charities.

Key standards of care

Lupus patients should be referred to a physician with experience in managing lupus who can confirm the diagnosis, assess the level of disease activity and provide advice on treatment and monitoring of the disease, its complications and side effects of therapy. Managing immunosuppressive therapies and their potential toxicities in patients with lupus can be a considerable challenge due to the risk of infection, difficulties with attribution of cytopenias to lupus or cytotoxic drugs, and difficulties in distinguishing manifestations of lupus disease activity from damage and co-morbid conditions. Input from a multidisciplinary team including nurse specialists and physiotherapists is usually required, and management may involve a variety of specialists, including rheumatologists, nephrologists, dermatologists, haematologists, cardiologists, chest physicians, neurologists, obstetricians, podiatrists and occupational therapists working as part of collaborative clinical networks involving regional specialist centres, local hospitals and GPs.

It is important to get patients to a low level of disease activity, if not remission, using HCQ, immunosuppressants and the least amount of CSs possible, in order to reduce cumulative damage from the disease and its treatment with CSs [71]. If drug treatment is not working within the expected time frame, it is important to consider adherence to treatment and adjusting the therapy to reduce the accumulation of chronic damage.

Patients need personalized advice, written information and education about the disease and its drug treatment from members of the multidisciplinary team, including specialist nurses and an individual to contact in the event of new symptoms. Additional topics covered should include sun avoidance, adequate vitamin D intake, weight control, exercise, not smoking and other measures to reduce atherosclerotic risk factors, as well as cancer screening, contraception and pregnancy planning when the disease is under good control on appropriate treatment for conception.

Future research agenda

There is a need for more evidence to support decision-making in the management of lupus patients. The guideline development group identified certain priorities for research into lupus to help address this issue, and these are shown in Table 8.

Mechanism for audit of the guideline

To assess compliance with these guidelines, an audit proforma is available on the British Society for Rheumatology website.

Funding: No specific funding was received from any funding bodies in the public, commercial or not-for-profit sectors to carry out the work described in these guidelines.

Disclosure statement: D.D.'C. has undertaken consultancies and received honoraria from GlaxoSmithKline/Human Genome Sciences and Roche, has been a member of the speakers' bureau for GlaxoSmithKline/Human Genome Sciences, Union Chimique Belge (UCB) and Eli Lilly and has received research grant support from Aspreva/Vifor

Guidelines

BSR and BHPR guideline for the prescription and monitoring of non-biologic disease-modifying anti-rheumatic drugs

Jo Ledingham[1], Nicola Gullick[2], Katherine Irving[2], Rachel Gorodkin[3], Melissa Aris[3], Jean Burke[4], Patrick Gordon[2], Dimitrios Christidis[5], Sarah Galloway[6], Eranga Hayes[7], Andrew Jeffries[8], Scott Mercer[9], Janice Mooney[10], Sander van Leuven[11] and James Galloway[12]; on behalf of the BSR and BHPR Standards, Guidelines and Audit Working Group

Key words: rheumatic disease, DMARDs, safe prescribing, treatment monitoring, methotrexate, co-morbidity, drug toxicity, shared care.

Executive Summary

Scope and Purpose of the Guideline

Need for guideline

The mainstay of treatment for inflammatory rheumatic disease involves DMARDs. The last 30 years have seen enormous shifts in the use of DMARDs, with earlier initiation in disease course as well as combination strategies. Many of the drugs used have potential for harm as well as benefit. Appropriate screening prior to DMARD initiation, as well as vigilant monitoring during therapy, are required to minimize the risk of harm. This current guideline supersedes the previous 2008 BSR/BHPR guideline [1].

Objectives of guideline

The aim is to provide evidence-based recommendations, which do not imply a legal obligation, for clinicians to follow when prescribing synthetic, non-biologic, anti-rheumatic drugs commonly used in management of multi-system rheumatic conditions.

NICE has accredited the process used by the BSR to produce its guidance for the use of non-biologic DMARDs. Accreditation is valid for 5 years from 10 June 2013. More information on accreditation can be viewed at www.nice.org.uk/accreditation. For full details on our accreditation visit: www.nice.org.uk/accreditation.

DMARDs covered by this guideline

The following DMARDs are covered in this guideline: apremilast, AZA, CSA, HCQ, LEF, mepacrine, MTX, Minocyline, MMF, sodium aurothiomalate/myocrisin (gold), SSZ and tacrolimus.

Target audience

The target audience is health professionals directly involved in managing patients with rheumatic disease in the UK, including rheumatologists, specialist nurses, pharmacists and general practitioners.

The areas the guideline does not cover

This guideline does not cover the indications for DMARD therapy or the use of biologic therapy and other selective non-biologic DMARDs (e.g. kinase inhibitors). The guideline also does not cover prescribing in relation to pregnancy because this is covered by an existing guideline [2, 3].

Key recommendations from the guideline

Specific questions were considered in relation to each drug. What baseline screening is needed prior to drug initiation? What impact does co-morbidity have for prescribers? What routine monitoring is needed? When should therapy be interrupted? Recommendations based on systematically reviewed evidence are given below. A description of evidence and full recommendations are given in the full guideline, available at *Rheumatology* online.

Generic Recommendations before Commencing any DMARD

(i) The decision to initiate DMARDs should be made in conjunction with the patient/carer and be supervised by an expert in the management of rheumatic diseases (GRADE 1B, 100%).
(ii) Patients should be provided with education about their treatment to promote self-management (GRADE 1B, 100%).
(iii) When appropriate, patients should be advised about the impact of DMARD therapy upon fertility, pregnancy and breastfeeding (GRADE 1B, 100%).
(iv) Baseline assessment should include height, weight, blood pressure and laboratory evaluation [full blood count (FBC), calculated glomerular filtration rate (GFR), alanine aminotransferase (ALT) and/or asparate aminotransferase (AST), albumin; GRADE 1C, 97%].
(v) Patients should be assessed for co-morbidities because these may influence DMARD choice, including evaluation for respiratory disease and screening for occult viral infection (GRADE 1C, 97%).
(vi) Vaccinations against pneumococcus and influenza are recommended (GRADE 1C, 97%).

Drug-specific Recommendations

(i) MTX: All patients should be co-prescribed folic acid supplementation at a minimal dose of 5 mg once weekly (GRADE 1B, 97%).
(ii) AZA: Patients should have baseline thiopurine methyltransferase (TPMT) status assessed (GRADE 1A, 97%).
(iii) HCQ: Patients should have baseline formal ophthalmic examination, ideally including objective retinal assessment for example using optical coherence tomography, within 1 year of commencing an antimalarial drug (GRADE 2C, 88%).

Prescribing DMARDs in Patients with known Co-morbidities

(i) Pre-existing lung disease is not a specific contraindication to DMARD therapy; however, caution is advised when using drugs associated with pneumonitis in patients with poor respiratory reserve (GRADE 1B, 95%).
(ii) In patients with deranged liver biochemistry, hepatotoxic DMARDs should be used with caution, with careful attention to trends in test results (GRADE 1C, 100%).
(iii) In patients with impaired liver synthetic function (e.g. cirrhosis), DMARD therapy should be used with extreme caution (GRADE 1C, 97%).
(iv) Patients with chronic viral hepatitis infection should be considered for anti-viral treatment prior to immunosuppressive DMARD initiation (GRADE 1B, 99%).
(v) DMARDs must be used with caution in chronic kidney disease, with appropriate dose reduction and increased frequency of monitoring (GRADE 1C, 97%).
(vi) Cardiovascular disease and prior malignancy are not considered contraindications to DMARD therapy (GRADE 1C, 95%).

Recommended DMARD Blood Monitoring Schedule when Starting or Adding a New DMARD

(i) Check FBC, creatinine/calculated GFR, ALT and/or AST and albumin every 2 weeks until on stable dose for 6 weeks; then once on stable dose, monthly FBC, creatinine/calculated GFR, ALT and/or AST and albumin for 3 months; thereafter, FBC, creatinine/calculated GFR, ALT and/or AST and albumin at least every 12 weeks. More frequent monitoring is appropriate in patients at higher risk of toxicity (GRADE 2B, 97%).
(ii) Dose increases should be monitored by FBC, creatinine/calculated GFR, ALT and/or AST and albumin every 2 weeks until on stable dose for 6 weeks then revert to previous schedule (GRADE 2B, 97%).
(iii) Exceptions/additions to the monitoring schedule for specific DMARDs are included in Table 1 (GRADE 2B and C, 100%).

Table 1 Summary of monitoring requirements

Drug	Laboratory monitoring	Other monitoring
Apremilast	No routine laboratory monitoring	None
AZA	Standard monitoring schedule[a]	None
Ciclosporin	Extend monthly monitoring longer term[b]	BP and glucose at each monitoring visit
Gold	Standard monitoring schedule[a]	Urinalysis for blood and protein prior to each dose
HCQ	No routine laboratory monitoring	Annual eye assessment (ideally including optical coherence tomography) if continued for >5 years
LEF	Standard monitoring schedule[a]	BP and weight at each monitoring visit
Mepacrine	No routine laboratory monitoring	None
MTX	Standard monitoring schedule[a]	None
MTX and LEF combined	Extend monthly monitoring longer term[b]	None
Minocycline	No routine laboratory monitoring	None
Mycophenolate	Standard monitoring schedule[a]	None
SSZ	Standard monitoring schedule for 12 months then no routine monitoring needed	None
Tacrolimus	Extend monthly monitoring longer term[b]	BP and glucose at each monitoring visit

[a]Standard monitoring as per recommendations I and II for DMARD blood monitoring schedule when starting or adding a new DMARD. [b]Patients who have been stable for 12 months can be considered for reduced frequency monitoring on an individual patient basis. BP: blood pressure.

Perioperative DMARD Management

(i) Steroid exposure should be minimized prior to surgical procedures, and increases in steroid dose to prevent adrenal insufficiency are not routinely required (GRADE 2B, 95%).

(ii) DMARD therapy should not routinely be stopped in the perioperative period, although individualized decisions should be made for high-risk procedures (GRADE 2B, 95%).

Intercurrent Infections

(i) During a serious infection, MTX, LEF, SSZ, AZA, apremilast, MMF, CSA and tacrolimus should be temporarily discontinued until the patient has recovered from the infection (GRADE 1A–C, 97%).

Recommendations for Shared Care Agreements

(i) The prescriber has responsibility for ensuring patients are adhering to monitoring guidance (GRADE 1C, 97%).

(ii) When prescribing takes place in primary care, it should be supported by local written shared care agreements, highlighting responsibilities of each party (patient, secondary care, primary care; GRADE 1C, 97%).

(iii) Contact rheumatology team urgently and consider interruption in treatment if any of the following develop: white cell count $<3.5 \times 10^9$/l; mean cell volume >105 fL; neutrophils $<1.6 \times 10^9$/l; creatinine increase >30% over 12 months and/or calculated GFR <60 ml/min; unexplained eosinophilia $>0.5 \times 10^9$/l; ALT and/or AST >100 U/l; platelet count $<140 \times 10^9$/l; unexplained reduction in albumin <30 g/l (GRADE 1C, 99%).

As well as responding to absolute values in laboratory tests, it is also relevant to observe trends in results (e.g. gradual decreases in white blood cells or albumin, or increasing liver enzymes).

For clinically urgent abnormalities, emergency access to specialist rheumatology advice, with response within one working day, should be available as per National Institute for Health and Care Excellence guidelines.

Funding: No specific funding was received from any bodies in the public, commercial or not-for-profit sectors to carry out the work described in this manuscript.

Disclosure statement: J.G. has received honoraria from MSD and Pfizer. J.M. has received honoraria from Bristol Myers Squibb and Pfizer. S.M. received honoraria from AbbVie, Pfizer, Roche and MSD. All other authors have declared no conflicts of interest.

Supplementary Data

The full guideline is available as supplementary data at *Rheumatology* Online.

Recognizing the clinical triad and dural calcification in adult hypophosphatasia

A 49-year old man who was treated for presumptive ankylosing spondylitis since adolescence presented with a 6 month history of thigh and knee pain. Clinically he had limited lumbar spine movement and patellar tenderness.

Laboratory indices revealed low serum alkaline phosphatase (17 U/l) but normal calcium, phosphate, parathyroid hormone, 25(OH)D and creatinine. HLA-B27 was negative and radiographic sacroiliitis was not present. Lumbosacral spine X-rays showed DISH-like changes (posterior longitudinal ligament calcification, paravertebral bridging, linear calcification and vertebral body hyperostosis). There were proximal right femur and bilateral patellae fractures. A CT scan of his lumbar spine showed spinal dural calcification (Fig. 1). Elevated urinary phosphoethanolamine (PEA; 47 μmol/mmol creatinine) confirmed the diagnosis of adult hypophosphatasia [1, 2]. A review of his family members revealed two siblings with chronic back pain, early loss of deciduous teeth, fragility fractures, low serum alkaline phosphatase, elevated urinary PEA and calcification of the posterior longitudinal ligaments.

A triad of low alkaline phosphatase, pathologic fractures and ectopic calcification should alert the physician to adult hypophosphatasia [1, 2]. In this case, the unusual finding of spinal dural calcification differentiated adult hypophosphatasia from other spine and metabolic bone diseases, thus aiding in diagnosis.

Key words: rheumatoid arthritis, psoriatic arthritis, psoriatic arthritis, ankylosing spondylitis, biologic, Anti-TNF, safety

Introduction

The use of biologic therapies has transformed the management of inflammatory arthritis (IA). In contrast to conventional systemic DMARDs (csDMARDs) traditionally used to treat inflammatory disease, these agents offer a targeted approach, and their widespread use has resulted in disease remission becoming an increasingly achievable goal. Biologic therapies are not without potential risk, and hence it is important that clinicians are aware of these risks and ensure that appropriate precautions are taken to minimize them. Information on the safety of biologic therapies continues to be collected through national registries, clinical and cohort studies and case series and reports.

This guideline supersedes the previous BSR/BHPR anti-TNF [1], rituximab (RTX) [2] and tocilizumab (TCZ) [3] guidelines and has been developed in line with the BSR Guidelines Protocol.

Scope and purpose

Background and need for guideline

In 2001, The British Society of Rheumatology published its first guidelines on the safety of anti-TNF agents in RA. This was subsequently updated in 2005 [4], and most recently in 2010 [1]. These guidelines covered the indications and precautions for the use of anti-TNF agents, and the action that should be taken in the case of an adverse event. The initial guidelines focused on the then-available first generation anti-TNF drugs (infliximab (INF), etanercept (ETN) and adalimumab (ADA)) in RA. This was then expanded in the 2010 guideline to include the newer anti-TNF agents, golimumab and certolizumab. Separate guidelines covering the use and safety of RTX [2] and TCZ [3] in RA were published in 2011 and 2014, respectively.

NICE accredited
www.nice.org.uk/accreditation

NICE has accredited the process used by the BSR to produce its guidance on the safety of biologic DMARDs in inflammatory arthritis. Accreditation is valid for 5 years from 10 June 2013. More information on accreditation can be viewed at www.nice.org.uk/accreditation. For full details on our accreditation visit: www.nice.org.uk/accreditation.

The previous 2010 BSR/BHPR biologics safety guideline focused solely on anti-TNF inhibitors for RA. While most safety evidence, especially long-term observational data, exists for the first generation anti-TNF agents in RA, since the last guideline there has been significant new information from clinical studies regarding the safety of both anti-TNF agents and the newer non-TNF biologic DMARDs, both in RA and in other licensed IA indications. In light of this, the 2010 guideline working group lead, and a new guideline working group confirmed, the need for an updated guideline combining the wider spectrum of biological agents used at present across their multiple approved indications.

Objectives of guideline

The purpose of this guideline is to provide evidence-based recommendations for the safe use of biologic therapies in adults (aged >18 years). Although the majority of published safety data still concern the use of first-generation anti-TNF agents in RA, this guideline has been expanded from the previous to cover the safety aspects of all biologic therapies (approved by the National Institute for Health and Care Excellence (NICE) as of June 2016; Table 1) for the treatment of RA, PsA and axial spondyloarthritis (SpA) including AS [referred to as inflammatory arthritis (IA) henceforth]. Therapies approved by NICE after June 2016, such as secukinumab, sarilumab and the Janus kinase inhibitors, are not included.

This guideline highlights several specific safety areas including recommendations for baseline screening prior to initiation, recommendations for monitoring, the implications of co-morbid disease and ageing, vaccinations and the management of biologic therapies in specific situations such as infection, malignancy and the peri-operative window.

Biologic therapies covered by this guideline (in alphabetical order) are shown in Table 1. Individual drug Summary of Product Characteristics (SPCs) are available online at www.medicines.org.uk, and can be used alongside this guideline.

The following indications are covered by this guideline: RA, PsA and axial SpA, including AS.

Target audience

This guideline is aimed at secondary health care professionals who are involved in the management of patients with IA receiving biologic therapies. This may include rheumatologists, rheumatology specialist nurses and allied health professionals, specialist pharmacists, rheumatology speciality trainees and patients. General practitioners, physicians in other specialties and surgeons who manage patients treated with biologic therapies may also find this guideline useful.

Table 1 Biologic therapies covered by this guideline

Biological therapy	Abbreviation	Mechanism of action
Abatacept	ABA	CTLA4-Ig
Adalimumab	ADA	Anti-TNF α
Certolizumab pegol	CZB	Anti-TNF α
Etanercept	ETN	Anti-TNF α
Golimumab	GOL	Anti-TNF α
Infliximab	INF	Anti-TNF α
Rituximab	RTX	Anti-CD20
Tocilizumab	TCZ	Anti-IL-6 receptor
Ustekinumab	UST	Anti-IL-12/IL-23

The areas the guideline does not cover

This guideline does not cover specific indications for biologic therapy in IA; this has been described in national and international disease-specific recommendations, as well as NICE guidance (www.nice.org.uk).

The guideline does not cover the safety aspects of csDMARDs. This has been recently updated in the BSR/BHPR non-biologic DMARD guidelines [5]. The guideline does not cover the use of biologic therapy for conditions other than RA, axial SpA including AS and PsA, nor safety in individuals aged <18 years. The safety of biologics in the context of pregnancy and breastfeeding is not covered here; this has recently been covered in the BSR/BHPR Prescribing Drugs in Pregnancy guidelines [6]. Finally, the guideline does not specifically cover the safety of biosimilar preparations of branded biologics; until further clinical data are available, the safety recommendations we propose for originator biologics can be applied to their biosimilar counterparts. Patients should be made aware of the potential switch to biosimilar preparations. The requirement for brand name prescribing and entry of patients into registries is essential to ensure ongoing pharmacovigilance including the collection of long-term observational safety data in this area.

Stakeholder involvement

This guideline was commissioned by the BSR Standards, Guidelines and Audit Working Group. A Guideline Working group (GWG) was created, consisting of a chair, Dr Chris Holroyd, alongside representatives from relevant stakeholders (Table 2). In accordance with BSR policy, all members of the GWG made declarations of interest, which is available on the BSR website.

Involvement and affiliations of stakeholder groups

The GWG was composed of rheumatology consultants from various clinical backgrounds, rheumatology specialty trainees, rheumatology nurse specialists and a patient representative. All members contributed to the development of key questions on which to base the search strategy, guideline content, recommendations and strength of agreement (SOA).

Rigour of development

This guideline has been developed in line with BSR's guideline protocol. A comprehensive literature search was undertaken by two reviewers, using MEDLINE, Cochrane, PubMed and EMBASE databases with specific search terms (Table 3). The reference lists of retrieved articles were manually searched for additional papers

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

Elizabeth Curtis	Clinical Research Fellow	MRC Lifecourse epidemiology Unit, University of Southampton
Christopher Chan	Specialty trainee	University Hospital Southampton
Mohammed A Yusuf	Specialty trainee	Mid Essex Hospitals NHS Trust
Anna Litwic	Consultant Rheumatologist	Salisbury District Hospital
Susan Smolen	Rheumatology research nurse	Mid Essex Hospitals NHS Trust
Joanne Topliffe	Rheumatology research nurse	Mid Essex Hospitals NHS Trust
Sarah Bennett	Rheumatology nurse specialist	University Hospital Southampton
Jennifer Humphreys	NIHR Academic Clinical Lecturer in Rheumatology	Arthritis Research UK Centre for Epidemiology, University of Manchester
Muriel Green	Patient Representative	
Jo Ledingham	Consultant Rheumatologist	Queen Alexandra Hospital, Portsmouth

and these were included if appropriate. All searches were performed up to the end of June 2016. Abstracts from BSR, EULAR and ACR annual conferences up to and including EULAR 2016 were also included.

Two thousand eight hundred and sixty-nine articles were identified from the literature search; after removal of duplicates, 560 were eligible for detailed review. Two reviewers independently extracted information from relevant papers using data extraction tables. Only articles in the English language containing information on the safety of biologic therapies were included. Two hundred and eighty-nine articles were finally included in the guideline.

The guideline was developed and drafted via a series of telephone conference calls and face-to-face meetings, using the retrieved literature to underpin and facilitate discussions. Due to the breadth of the guideline, designated members of the GWG were divided into sub-groups to lead on specific sections of the guideline. One subgroup led the anti-TNF section, another the RTX and abatacept (ABA) section, and the third group led the TCZ and ustekinumab (UST) sections.

Grading the evidence

The GRADE method was used to assess the quality of evidence and the strength of recommendation [7]. Accompanying each recommendation in this guideline, in brackets, is the strength of recommendation, quality of evidence and SOA. Each subgroup produced GRADE scores for their sections, which was then distributed to and ratified by the entire GWG.

Strength of recommendation

Using GRADE, recommendations were categorized as either strong (denoted by 1) or weak (denoted by 2), according to the balance between benefits and risks. A strong recommendation was made when the benefits clearly outweigh the risks (or vice versa). A weak recommendation denotes that the benefits are more closely balanced with the risk or more uncertain.

Quality of evidence

Using the GRADE approach, the quality of evidence was determined as either high (A), moderate (B) or low/very low (C) reflecting the confidence in the estimates of benefits or harm.

High quality (A): typically generated from well-conducted meta-analyses, randomized controlled trials (RCTs) or other overwhelming evidence (such as large, well-executed observational studies with a low risk of bias). Further research is very unlikely to change confidence in the estimate of effect.

Moderate quality (B): usually from randomized controlled trails or observational studies with important limitations. Further research is likely to have an important impact on and may change the estimate of effect.

Low quality (C): usually from observational studies, or randomized controlled trials with major limitations. Further research is very likely to have an important impact on the confidence in the effect estimate and is likely to change the estimate. Very low quality evidence is usually derived from observational studies with serious limitations or from non-systematic observations (such as case reports and case series).

SOA

Each draft recommendation was evaluated by all members of the GWG. Based on the strength of recommendation and level of evidence, each recommendation was subject to a vote by all members of the GWG; a scale of 1 (no agreement) to 10 (complete agreement) was used. Only recommendations with a mean SOA score of $\geqslant 7$ plus $\geqslant 75\%$ respondents scoring $\geqslant 7$ were included. The SOA is presented next to the GRADE score for each

recommendation as a percentage (e.g. 100% would imply all responses were 10/10).

Limitations of this guideline

The literature search excluded any articles not available in English language and any non-human studies. In addition, there were a very small number of articles identified through the search strategy that we were unable to obtain through university library channels.

Plan for review

In line with BSR's guideline protocol, this guideline will be updated in 3–4 years, but if there is a significant change in the evidence base then an earlier update may be undertaken.

The guideline

To date, most long-term observational studies have focused on the safety of first generation anti-TNF agents (INF, ETN and ADA) in RA. In some areas, there is an increasing body of evidence regarding the safety of non-TNF biologic agents; however, there remains a paucity to guide many clinical scenarios. Where appropriate the evidence underpinning our recommendations has been divided into two sections: anti-TNF biologics and non-anti-TNF biologics.

Generic recommendations

(i) The decision to initiate a biologic should be made in conjunction with the patient/carer and initiated by an expert in the management of rheumatic disease (grade 1C; SOA 99%).

Biologic therapy for IA can be prescribed when patients meet the respective NICE recommendations. As NICE restrict eligibility and there are potential risks (as discussed through this document), as well as benefits from biologic therapies, decisions to initiate therapy should be made by a consultant rheumatologist. Following national initiatives and guidance, patients and/or their carers should be actively involved in the decision making processes.

(ii) Patients should be provided with education about their treatment to promote self-management (grade 1B, SOA 99%).

A Cochrane review in 2002 demonstrated that education had a positive effect in terms of both patient reported outcome and objective measures of clinical response; however, the benefits were not observed during a longer duration of follow-up [8]. The Department of Health has estimated that the average cost of education and self-management is £125/person and would save costs of £244/person on average [9].

Rheumatologists should therefore offer patients with IA the opportunity to discuss their condition and the risks and benefits of treatments both at diagnosis and throughout the course of their disease. Patients with IA should be offered verbal and written information to improve their understanding of their specific condition and its management. For those patients who would like further information, participation in existing educational activities including self-management programmes is recommended [10].

(iii) Patients should be assessed for co-morbidities as these may influence biologic choice, including evaluation for respiratory disease and screening for infection (grade 1C, SOA 99%).

Comorbid conditions such as respiratory disease and underlying infection have significant implications for both csDMARD and biologic prescribing. Patients should be assessed for such comorbidities at baseline and reviewed regularly (at their annual review and upon changes in treatment as a minimum). Further information is detailed later in this document.

(iv) Patients should have direct access to their specialist centre [e.g. via an advice line (Helpline)] for advice within one working day (grade 1C, SOA 98%).

The NICE quality standard (QS33) for the management of RA states that patients experiencing flares in their condition or a drug-related side effect should be offered, and be able to obtain, direct advice from their rheumatology service [11]. Advice should be available within one working day and when required prompt action should be taken to ensure patients' safety and optimize management of their RA. The principles behind this recommendation should also be applied to the other IA problems covered by this guideline.

(v) Clinicians should be encouraged to recruit patients to the appropriate biologic therapy registry, with patient consent (grade 1C, SOA 98%).

Although RCTs are considered the gold standard for the demonstration of biologic therapy efficacy, they are limited in their use for collecting safety data. There are several reasons for this—small patent numbers in RCTs make the detection of rare side effects difficult, short duration of follow-up leads to challenges in the detection of delayed side effects, homogeneous patient recruitment may not be representative of real life, exclusion criteria hamper recruitment of patients with important co-morbidities and RCTs are generally powered to detect efficacy outcomes, rather than significant safety signals. It is important that patients are recruited to the appropriate national biologic therapy registries [such as the British Society for Rheumatology Biologics Register for RA (BSRBR-RA) and the British Society for Rheumatology Biologics Register for AS (BSRBR-AS)], to enable long-term collection of real-life safety data on a large scale.

For patients prior to treatment with a biologic

Pre-treatment investigations

(i) Baseline assessment for all should include (grade 1C SOA 98%): laboratory evaluation of full blood count (FBC), creatinine/calculated glomerular filtration rate (GFR), alanine aminotransferase (ALT) and/or aspartate aminotransferase (AST), albumin,

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

tuberculin skin test (TST) or interferon-gamma release assay (IGRA) or both as appropriate, hepatitis B and C serology, and a chest radiograph.

Baseline assessment in both csDMARD and biologic prescribing acts as a screening tool for underlying conditions such as lung, renal or hepatic disease and also provides a reference point for future comparison. While the pick-up rate of routine investigations in a healthy individual is low, there is an increased incidence of significant abnormalities in RA patients, due to their increased overall burden of comorbidities [12]. Screening for TB and hepatitis are discussed in more detail in the mycobacterium tuberculosis and hepatitis sections.

(ii) Patients receiving RTX: baseline immunoglobulins (IgA, IgG and IgM) are recommended prior to initiation (grade 1A, SOA 98%).

Few patients would be expected to have low Ig levels before the start of RTX therapy: $\leqslant$2.2% in one study of 3595 patients [13]. However, several studies have found that a low level of immunoglobulins, especially IgG, is associated with a higher risk of neutropaenia and infection in patients receiving RTX [13–16].

(iii) Patients receiving TCZ: a baseline lipid profile is recommended prior to initiation. If abnormal, lipid lowering treatment should be initiated as per local guidance (grade 2A, SOA 99%).

Blockade of the IL-6 receptor by TCZ is associated with an increase in lipid parameters compared with baseline. Despite the increase in low-density lipoprotein (LDL)-cholesterol, trial data seem to indicate that the ratio of total cholesterol: high-density lipoprotein (HDL)-cholesterol remains unchanged [17]. A *post hoc* retrospective pooled analysis [18] of 3986 patients who received TCZ found 0.34 independently adjudicated major adverse cardiovascular events (MACE) per 100 patient-years in 24 weeks of follow-up. The study found an association between baseline total cholesterol: HDL-cholesterol ratio and MACE, with poor RA disease control associated with a higher risk of future MACE.

Pre-treatment management of and screening for co-morbidity

Infection. In general (recommendations for *Mycobacterium tuberculosis*, viral hepatitis and HIV are discussed separately):

(i) Biologics should not be initiated in the presence of serious active infections (defined as requiring intravenous antibiotics or hospitalization (grade 1B, SOA 98%).

Patients with RA, especially those with severe disease and extra-articular manifestations, have a higher risk of infection, estimated at double the risk of the general population [19]. Patients with severe disease, who already have a higher risk of infection, are more likely to receive biologic therapies; hence when evaluating the association between a drug and infection risk, it can be difficult to determine whether the infection risk is drug-related or is in keeping with that expected for the disease severity.

The most recent Cochrane review of 106 controlled trials, including 42 330 patients with RA, found that patients receiving standard dose biologic therapies were at a 27% higher odds of serious infection compared with controls [20], findings consistent with the same author's earlier Cochrane review [21].

Anti-TNF biologics. Of all the studies evaluating the safety of biologic therapies, those investigating the association between anti-TNF agents and infection risk are the most numerous, the majority of which have focused on the use of the first generation anti-TNF's (INF, ETN and ADA) in RA. Although there have been some inconsistencies between the results from various analyses, the majority of studies have found a significant association between anti-TNF drugs in patients with RA and a higher risk of serious infection.

Observational data from several national registries, including the BSRBR-RA [22], US Coronna registry [23] and the Spanish BIOBADASER 2.0 [24], have shown a significant positive association between anti-TNF agents and serious infection in RA. BSRBR-RA included data from 11 798 RA patients receiving ADA, ETN or INF, and 3598 csDMARD controls. The incidence of serious infection in the TNF group was 4.2/100 patient-years *vs* 3.2/100 patient-years in the DMARD group. The adjusted hazard ratio for serious infection in the TNF group was 1.2 (95% CI: 1.1–1.5) [22]; the highest risk of infection was in the first 6 months of treatment. This evidence has furthermore been supported by results from recent meta-analyses by Bernatsky *et al*. [25] and Michaud *et al*. [26], which both reported an approximate 1.4-fold increased risk of infection in RA patients treated with anti-TNF agents compared with csDMARD controls.

There is a relative paucity of long-term observational data investigating the risk of infection in other types of IA, such as AS and PsA. A Cochrane review [27] and a meta-analysis of RCTs [28] in AS, and two meta-analyses of RCTs in PsA [29, 30] found no elevated risk of serious infection with anti-TNF therapy used in these conditions; however, the analyses included a low number of RCTs compared with the RA data (between 6 and 21 studies) and event rates of infection were low making the studies underpowered to show a significant association. Given the theoretical risks, the advice substantiated by evidence for RA should be applied to patients with other IA problems.

Non-anti-TNF biologics. Comparatively fewer studies have examined the association between serious infection and non-anti-TNF biologic therapy. Longer term data on infection risk with these drugs is required, and until such information is available it would be prudent to take similar precautions with these drugs as with anti-TNF therapy.

With regards to RTX, the most recent observational data, from the US Coronna registry [31], showed similar rates of infection in 265 patients receiving RTX compared with 739 patients receiving anti-TNF therapy (event rate of 37.7 *vs* 41 events per 100 person-years). However, a previous RCT meta-analysis of the risk of infection with RTX

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

[32], which analysed data from three studies, did not show an increased risk of serious infection in patients receiving RTX compared with placebo. An observational French study found that the risk was highest in the first 6 months after commencing treatment [14]. Long-term safety after 9 and 11.5 years was assessed and was deemed no higher than MTX and placebo [13, 33].

TCZ has been shown to increase the risk of serious infection in patients with RA. The risk is likely to be similar to anti-TNF therapy although long-term comparative data are not available. In the ADACTA study [17], which was a double-blinded parallel arm trial comparing the efficacy and safety of ADA and TCZ as monotherapy, the rates of serious infection were similar in both groups (3%). A systematic review by Campbell *et al*. [34] showed a slightly increased risk of infection with TCZ 8 mg/kg compared with controls, but similar to rates of infection with other biologics. Infection risk with the lower dose of 4 mg/kg was lower.

Yun *et al*. [35] conducted a retrospective cohort study using Medicare data including 23 784 patients on five anti-TNFs as well as ABA, RTX and TCZ, looking at incidence of hospitalized infection. The likelihood of being admitted to hospital with an infection on TCZ was lower than for INF, RTX and ETN, but higher than for ABA.

A study that pooled data from the double-blind and open-label phases of five clinical trials of s.c. ABA reported an incidence rate (IR) of serious infections of 1.79 (95% CI: 1.42, 2.24), which did not significantly change over time (mean exposure 27.3 months) [36]. This is in keeping with previous data for i.v. ABA [37]. A 2009 meta-analysis suggested that the risk of serious infections during ABA treatment [odds ratio (OR) = 1.35, 95% CI: 0.78, 2.32 *vs* placebo) is not significantly increased [32].

At present there is a lack of long-term observational data concerning the risk of serious infection with UST.

Given the theoretical risks with all biologics and the risk presented with the longer established treatments, the advice is that biologics should not be started in the presence of serious infection.

(ii) Use biologics with caution in patients at high infection risk after discussing risks and benefits (grade 1B, SOA 99%).

Several observational studies have identified factors that may increase an individual's risk of infection with biologic therapies. This additional risk may be unacceptable to patients, and needs to be carefully weighed up against the perceived benefits when prescribing biologic therapies.

Anti-TNF biologics. Comorbidities such as chronic obstructive pulmonary disease (COPD) [24, 38], interstitial lung disease (ILD) [24] and renal failure [24] have been associated with higher rates of serious infection in RA patients receiving anti-TNF agents. Concomitant steroid use has also been repeatedly associated with higher infection risk [24, 38]; however, in many patients the introduction of biologic therapies will enable reduction or cessation of steroid exposure. Although some studies have identified older age as an independent risk factor for serious infection with anti-TNF drugs, two recent studies have been reassuring. Data from BSRBR-RA showed that while older patients (aged >75 years) had a higher absolute risk of infection, there was no increased relative risk of serious infection on anti-TNF agents [22]. Similarly, no significant difference in serious infection rate was observed in a Swiss cohort of RA patients receiving anti-TNF therapy when divided into those above or below 65 years of age [39].

There is a lack of data concerning risk factors for serious infection in patients with other types of IA treated with anti-TNF therapy. Given the theoretical risks, the advice substantiated by evidence for RA should be applied to patients with other IA problems.

Non-anti-TNF biologics. The French AIR Registry, which analysed data from 1303 RTX-treated RA patients, found that rates of severe infection were significantly higher in those with chronic lung disease and/or cardiac insufficiency (OR = 3.0, 95% CI: 1.3, 7.3), extra-articular involvement (OR = 2.9, 95% CI: 1.3, 6.7) and low IgG level (<6 g/l) before initiation of RTX treatment (OR = 4.9, 95% CI: 1.6, 15.2) [14].

There is a lack of long-term observational data concerning risk factors for serious infection in patients with other types of IA treated with non-anti-TNF therapy; especially as UST is the only biologic within this category with a non-RA licence (for PsA). Given the theoretical risks, the advice substantiated by evidence for RA should be applied to patients with other IA problems.

(iii) Consider using ETN or ABA as a first-line biologic therapy in patients at high risk of infection (grade 2B, SOA 94%).

Anti-TNF biologics. There is some evidence from both RCTs and observational studies to suggest that the risk of serious infection may be lower with ETN compared with other anti-TNF agents. A meta-analysis of 44 RCTs found the odds of serious infection with anti-TNF agents to be lowest for ETN (pooled OR = 0.73, 95% CI: 0.45, 1.20 *vs* 1.42, 95% CI: 1.13, 178) for all anti-TNF agents combined) [26]. Several observational trials have also observed lower rates of serious infection with ETN, including a US claims database [40], BSRBR-RA [22], the Dutch DREAM registry [41], the Australian ARAD database [42] and the Italian GISEA registry [43].

Non-anti-TNF biologics. A low incidence of serious infection with ABA has been reported in long-term observational studies [36, 37] and a meta-analysis [44]. In the AMPLE study [45], an RCT comparing the safety and efficacy of s.c. ABA *vs* ADA in patients with RA over 2 years, numerically lower rates of infection were observed in the ABA arm (3.8%) compared with ADA (5.8%); however, this study was not powered to detect a significant difference in infection rates.

Mycobacterium tuberculosis

screening for TB before starting a biologic

(i) All patients require screening for tuberculosis (TB) before starting a biologic (grade 1B, SOA 98%).

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

Anti-TNF biologics. The increased risk of active TB and reactivation of latent TB associated with anti-TNF treatment, as demonstrated in a number of studies, has led to a requirement to screen for active and latent TB in patients before anti-TNF treatment is given [46–54]. A 2014 meta-analysis of RCTs [55] confirmed an increased risk of mycobacterial infections in patients on biologics (OR = 3.73, 95% CI: 1.72, 8.13) and that the risk varied with different agents [see recommendation (iii) for latent and reactivated TB).

Non-anti-TNF- biologics. Relatively few large long-term studies have investigated the risk of TB reactivation with non-anti-TNF biologics. Although the results from studies appear reassuring for this group of drugs with regards to TB reactivation, until more data are available, the advice given for anti-TNF therapy should be considered.

Data regarding the risk of reactivating TB with RTX look reassuring. The largest study to date, which combined data from clinical trials and long-term extension studies, reported only two cases of pulmonary TB among 3595 RA patients who had received RTX over a mean follow-up of 11 years [12]. A Taiwanese study of 56 patients (43 patients were presumed to be without latent TB infection, seven patients had latent TB and six patients had anti-TNF-associated TB) found that over a 1 year period of RTX therapy, no patient developed active TB [56]. A 2014 review [57] found no cases of active TB recorded in patients with RA and other rheumatic conditions treated with RTX and ABA, and in fact, argued against pre-screening for TB in patients receiving these two biologics.

Koike *et al*. [58] published safety data from an all-patient post-marketing surveillance programme in Japan in 2011. Out of a total of 3881 patients treated with TCZ (1794 patient-years), four cases of active TB were identified (0.22/100 patient-years). Cantini *et al*. [57] observed eight cases of active TB in 21 trials of patients with RA receiving TCZ.

Combined data derived from five RCTs of s.c. ABA in RA found that TB occurred rarely, with an IR of 0.09 (95% CI: 0.04, 0.25) among 1879 patients [36]; this is lower than that observed for other biologics [59].

Regarding UST, a safety analysis of 3117 patients from five phase III clinical trials across the USA, Europe and Asia identified 167 patients with latent TB. These patients received isoniazid prophylaxis prior to receiving treatment with UST. No cases of active TB resulted in the 12-week treatment period. However, cases of TB have been reported in patients on UST [60].

(ii) Screening for TB should include checking for previous TB exposure and treatment, performing a clinical examination, chest X-ray (CXR) and either a TST or an IGRA or both, as appropriate (grade 2C, SOA 98%).

(iii) For patients on immunosuppressive therapy with a normal CXR, a TST is *not* helpful, as immunosuppression hinders interpretation (grade 2C, SOA 98%).

(iv) Patients with an abnormal CXR, previous history of TB or TB treatment should be referred to a specialist with an interest in TB prior to commencing a biologic (grade 2C, SOA 99%).

(v) Immunocompromised patients screened for latent TB with an IGRA alone or together with a TST and found to have a positive result in either test should be considered for treatment prior to starting biologic therapy (grade 2C, SOA 96%).

Investigations for latent TB infection in a person exposed to *M. tuberculosis* but without active signs of TB are based on the TST or IGRA.

The TST involves an intradermal injection of purified protein derivative and measurement of skin erythema and induration, which corresponds to a delayed-type hypersensitivity reaction in patients with previous exposure to TB (including latent TB). Previous vaccination with BCG will also cause a skin reaction but of a lower magnitude than after exposure to TB.

IFN-γ release assays [two commercially available: QuantiFERON-TB Gold In-Tube assay (QFT) and T-SPOT.TB] measure IFN-γ release by T cells in blood samples mixed with mycobacterium TB antigens. QFT measures the IFN-γ concentration (IU/ml) using ELISA technology, whereas T-SPOT.TB reports the number of T cells producing IFN-γ (spot forming cells). T-SPOT.TB is also known as the TB ELISPOT (enzyme-linked immunospot assay).

The TST and IGRA measure the response of T cells to TB antigens. As a false-negative result occurs in 20–25% of patients with active pulmonary TB, these tests should not be used alone to exclude a diagnosis of active TB.

Identifying latent TB in patients due to start biologic treatment has been problematic as the TST and, to a lesser extent, IGRA assays are thought to be less reliable in immunosuppressed patients [61, 62]. Most studies comparing TST with IGRA performance in immunosuppressed populations suggest sensitivity and specificity of IGRA is superior to TST [63–66] but not all studies support this [67, 68]. In addition, IGRA positivity has been shown to be more closely related to TB risk than positive TST results. A recent meta-analysis of the performance of the two available IGRA tests (QFT and T-SPOT.TB/ELISPOT) *vs* TST in patients with rheumatic disease before starting biologic therapy reported pooled concordances between the QFT assay and TST of 72% (65–78%) and between T-SPOT.TB and TST of 75% (67–83%). It also showed that IGRAs have a lower false-negative and false-positive rate, compared with TST, particularly in patients treated with corticosteroids and those with a history of BCG vaccination [69]. Although two IGRA tests are commercially available, based on the present data, there is no robust evidence to recommend a preference for one over the other.

The true sensitivity or specificity of the TST or IGRA is uncertain because a gold standard test for the presence of latent TB is currently unavailable. However, a closer correlation has been found between IGRA and risk factors for latent TB infection, including personal history, TB contact history and a suggestive CXR [65, 70]. Some studies have suggested using only an IGRA when screening for latent TB because in immunosuppressed patients, it is more specific than the TST and may therefore reduce the proportion of patients needing chemoprophylaxis

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

[71, 72]. However, observational studies suggest that, given the discordance between these two types of test, use of one test may miss some patients with latent TB who would be identified by an alternative test [70, 73, 74]. Observational studies support the use of combination testing [61, 75].

Current international guidelines support screening all patients for latent TB before starting biologic therapy. However, given the inconclusive evidence available, the optimum screening strategy is unclear, with disagreement on whether to use an IGRA or TST, or both. In the UK, the 2016 guidance from NICE [76, 77] recommends testing all immunocompromised patients for latent TB with an IGRA alone or together with a TST—a positive result in either test should prompt consideration for treatment. However, the WHO recommends using either test and the European Centre for Disease prevention and control recommends using both [78, 79].

Screening with TST or IGRA is unhelpful in patients who have had treatment for active or latent TB. In this situation a chest X-ray and sputum examination will be sufficient, with input from a TB specialist.

Treatment of latent TB should be initiated after the possibility of TB disease has been excluded. The Centers for Disease Control and Prevention recommends treatment for latent TB in individuals with a positive IGRA result or a TST reaction of $\geqslant$5 mm, in immunosuppressed individuals (e.g. those on $>$15 mg/day of prednisolone for 1 month or longer and taking anti-TNFs), HIV-infected individuals, patients with organ transplants and individuals with fibrotic changes on CXR consistent with prior TB (cdc.gov/tb).

Treatment is also recommended in individuals with a positive IGRA or a TST reaction of $\geqslant$10 mm, including recent immigrants ($<$5 years) from high-prevalence countries, injection drug users and residents and employees in high-risk settings (e.g.: nursing homes and hospitals).

In addition, individuals with no known risk factors for TB may be considered for treatment of latent TB is they have a positive IGRA or a TST 15 mm or more. Targeted TB testing programmes are recommended among high-risk groups, with appropriate follow-up care.

The four treatment regimens for latent TB infection use isoniazid, rifapentine or rifampicin, and consultation with a TB expert is advised if the known source TB infection has drug-resistant TB.

TB drug treatment for the prevention of TB, also known as chemoprophylaxis, can reduce the risk of a first episode of active TB occurring in people with latent TB. Current evidence suggests that decisions about chemoprophylaxis should be based on the results of the TST and an IGRA. If either test is positive, it would be appropriate to treat with chemoprophylaxis while monitoring carefully for treatment-related side effects [76, 80, 81].

The majority of potential recipients of anti-TNF medication will have a normal CXR and will have been on immunosuppressive therapy thus hindering the interpretation of latent TB testing [82–84]. In these individuals, an individual risk–benefit calculation is recommended. If the annual risk of TB on anti-TNF treatment is higher than the risk of anti-TB therapy-induced hepatitis, then the risk–benefit analysis favours chemoprophylaxis; if lower, the risk–benefit calculation favours observation and investigation of symptoms [80]. The two chemoprophylaxis regimens commonly used in the UK are isoniazid for 6 months (6H) or rifampicin plus isoniazid for 3 months (3RH).

Latent and reactivated TB

(i) Patients should be treated with prophylactic anti-TB treatment prior to commencing a biologic (grade 1B, SOA 99%); therapy may be commenced after completing at least 1 month of anti-TB treatment and patients should be monitored every 3 months (grade 2C, SOA 91%).

(ii) Patients who have had previous inadequate treatment for active TB should be investigated for active TB. In these individuals even when active disease has been excluded, the annual risk of TB (reactivation) is much higher than the general population rate, so the risk–benefit analysis favours chemoprophylaxis (grade 1C, SOA 98%).

The above recommendation i and ii are based in part on expert opinion in the NICE guideline ‘Tuberculosis’ [76, 77] and the 2005 British Thoracic Society (BTS) guidelines [80]. While there is a consensus that all patients with latent TB should receive anti-TNF chemoprophylaxis prior to commencing a biologic, there is a lack of data regarding the point at which biologic therapy can then be started. The BTS guidelines suggest that a patient should receive a full course of anti-TB treatment before starting a biologic; however, while this is ideal, 3–6 months’ delay is likely to be unacceptable for the majority of patients due to the severity of their rheumatic disease. The BTS guidelines have not been updated since 2005, and since then clinical experience has developed. Current expert opinion suggests that biologic therapy can be started after competing at least 1 month of anti-TB therapy. This is primarily to ensure that anti-TB treatment is tolerated, especially in what is often a population over 55 years of age. Patients should be monitored every 3 months with close involvement with a TB specialist throughout.

Chemoprophylaxis for TB itself carries a small risk, with drug-induced hepatitis being the main issue, increasing with age and associated with increased mortality. It is important to exclude active TB disease before chemoprophylaxis is given, as there are concerns that single agent chemoprophylaxis given when active disease is present could lead to the development of drug resistance [67].

Two preventative treatment regimens in common use in the UK are isoniazid for 6 months (6H), or rifampicin plus isoniazid (3RH) for 3 months. Rifampicin and pyrazinamide for 2 months (2RZ) was a regimen used in the USA [85], but it had a very high rate of hepatitis with a number of fatalities reported [86]. Consequently, the choice of regimen is between 6H, which has a lower hepatitis rate, and 3RH, which is of shorter duration and with which there is thought to be better adherence and also less risk of drug resistance developing if active disease is present [87].

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

(iii) As TB reactivation risk is higher with anti-TNF mAb drugs (notably ADA and INF) than for ETN, consider ETN in preference for those who require anti-TNF therapy and are at high risk of TB reactivation (grade 1B, SOA 99%).

The risk of TB reactivation appears higher with the mAb INF and ADA than for ETN [45, 46, 48–51, 53], a finding confirmed with registry data [47, 52]. In the BSRBR-RA the rate of TB was higher with ADA (144 events/100 000 person-years) and INF (136 events/100 000 person-years) than with ETN (39 events/100 000 person-years) [47]. After adjustment, the incidence-rate ratio (IRR) compared with the ETN-treated patients was 3.1 (95% CI: 1.0, 9.5) for INF and 4.2 (95% CI: 1.4, 12.4) for ADA. In light of this, we suggest that ETN should be considered as a first-line anti-TNF treatment in patients at high risk of reactivation of latent TB.

The incidence of TB for the newer anti-TNFs (certolizumab pegol (CZB) and golimumab (GOL)) is less well documented. Cantini *et al.* [57] assessed the safety data of both GOL and CZB in patients with rheumatic disease and identified 8 cases of active TB in 3387 patients with rheumatic disease treated with GOL (7 of the 8 TB cases occurred in TB-endemic countries, where the TB incidence is 50–299 cases per 100 000 inhabitants) and 10 cases of active TB in 3167 patients with RA treated with CZB.

Active TB

(i) Patients with evidence of active TB should be treated before starting a biologic (1C, SOA 99%); therapy may be commenced after completing at least 3 months of anti-TB treatment and there is evidence that the patient is improving with evidence of culture negativity (grade 2C, SOA 91%).

Full compliance with anti-TB treatment should be supervised by a thoracic physician or infectious disease specialist, and ideally continued until the drug susceptibility profile of the organism in those with positive cultures is known. Furthermore, it would be preferable to delay anti-TNF treatment until completion of a full course of anti-TB treatment (this is based on the expert opinion from the BTS [80]).

HBV and HCV

(i) Patients should be screened for hepatitis B and C viral infection (grade 1C, SOA 98%).

Hepatitis B and C are blood-borne infections of the liver that can result in chronic liver disease and hepatocellular carcinoma. NICE currently recommends that all people who are at increased risk of hepatitis B and C infection are offered testing and vaccination [NICE Public health guideline (PH43): Hepatitis B and C testing: people at risk of infection]. Examples of people at increased risk of hepatitis B and C infection are shown in Table 4.

For hepatitis B in particular, additional groups at increased risk include people who may have been exposed to sexually acquired infection.

For hepatitis C in particular, additional groups at increased risk include people who received a blood transfusion before 1991 or blood products before 1986, when screening of blood donors for hepatitis C infection and heat treatment for inactivation of viruses were introduced.

Screening for HBV should include HBsAg and antibodies to hepatitis B core antigen (anti-HBc) and surface antigen (anti-HBs), followed by HBV DNA test if HBsAg or anti-HBc are positive. These results will dictate the level of monitoring and prophylaxis, which varies between occult HBV infection (i.e. HBsAg negative and anti-HBc positive or anti-HBs positive) and overt HBV infection (i.e. HBsAg positive).

Screening for HCV infection is at present based on the detection of anti-HCV antibodies. If anti-HCV antibodies are detected, HCV RNA, or alternatively HCV core antigen if HCV RNA assays are not available, should be determined to identify patients with on-going infection.

The prevalence of hepatitis B and C as comorbidities in patients with RA varies across the world, due to epidemiological variations in risk factors. In a French cohort of patients with early RA, the seroprevalence of HBV and HCV infection was reported as 0.12 and 0.86%, respectively [88]. A higher seroprevalence of 3% for HBV and 2% for HCV infection was recently reported in COMORA, an international cross-sectional study of comorbidities in RA [12].

Acknowledging that there are now effective therapies for viral hepatitis, there is a strong rationale for offering screening to all patients prior to commencing immunosuppression.

(ii) In patients who are HBV positive, a risk–benefit assessment should be undertaken, as biologics may be safe if appropriate anti-viral treatment is given, working closely with a hepatologist (grade 1C, SOA 99%).

Anti-TNF biologics

There are a few medium-quality systematic reviews of observational studies evaluating the risk of reactivation of hepatitis B in patients with HBV infection treated with anti-TNF therapy in the context of an IA. A systematic review [89] included 536 patients with occult or overt HBV infection and an underlying rheumatological or dermatological condition treated with INF, ETN or ADA. The pooled estimate of HBV reactivation was 4.2% (95% CI: 1.4, 8.2%) for all patients. When the meta-analysis was restricted to patients with RA, the pooled prevalence of HBV reactivation was slightly lower at 3.3% (95% CI: 0.7, 7.5%). HBV reactivation rates were higher in the overt HBV group *vs* the occult HBV group (15.4 *vs* 3%). These reactivation rates were similar to those reported in two other systematic reviews [90, 91]. In a case–control study of RA patients with occult HBV infection [92], the use of anti-TNF therapy was more frequent in those with HBV reactivation than not (86 *vs* 36%) $P = 0.008$, hazard ratio (HR) = 10.9 (95% CI: 1.4, 87.7).

Patients who are HBsAg negative and anti-HBc positive (or anti-HBs positive) are nonetheless deemed to have an occult infection as low-level HBV replication may persist, with detectable HBV DNA in the liver but generally not in the serum. The clinical relevance of this is unclear

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

Table 4 Risk factors for hepatitis B and C infection

People at higher risk of hepatitis B and C infection
People born or brought up in a country with an intermediate or high prevalence of chronic hepatitis B or C. This includes all countries in Africa, Asia, the Caribbean, Central and South America, eastern and southern Europe, the Middle East and the Pacific islands
People who have ever injected drugs
Men who have sex with men (particularly, HIV-positive men who have sex with men are at a greater risk of hepatitis C)
People in close contact with someone known to be chronically infected with hepatitis B or C
Prisoners, including young offenders

although immunosuppression may lead to HBV reactivation in these patients [93]. Therefore, where a decision is made to proceed with an anti-TNF agent on risk–benefit analysis, a rheumatologist should work closely with a hepatologist to ensure liver disease is fully assessed at baseline then monitored on treatment.

Several international groups have recommended that patents with overt HBV receiving immunosuppressive medicines should receive anti-viral prophylaxis [93, 94]. Perez-Alvarez *et al*. [95] found that of the reported cases of overt HBV patients treated with anti-TNF agents, HBV reactivation was 2.5-fold higher in patients not receiving prophylaxis (64 *vs* 26%). Of the 82 patients with overt HBV treated with an anti-TNF, five had acute liver failure, one required a liver transplant and four died. The European Association for the Study of the Liver suggest overt HBV candidates for immuno-suppressive therapy should be tested for HBV DNA levels and should receive pre-emptive anti-viral treatment during therapy (regardless of HBV DNA levels) and for 12 months after cessation of therapy. Occult HBV patients with detectable serum HBV should be treated like overt HBV patients [93].

Non-anti-TNF biologics

In patients receiving RTX, re-activation of HBV in patients with occult hepatitis B (HBsAg negative; anti-HBc positive) has been reported [96], with the authors suggesting that patients with sero-positivity for either occult or overt hepatitis B should be referred to a hepatologist.

A systematic review by Campbell *et al.* [34] found no increased risk of hepatitis B reactivation with TCZ; however, the number of cases was low and further long-term data are required. There are no data concerning the use of ABA and HBV.

There are very few published data on the use of UST in patients with chronic hepatitis B. In a small observational cohort of 14 with hepatitis B serology treated with UST, no increase in viral load was seen in patients who had received prophylaxis [97]. However, two out of seven patients (29%) who did not receive prophylactic anti-viral therapy were noted to have an increase in viral load. If clinically indicated, UST may be used in patients with hepatitis B following prophylactic anti-viral treatment.

In conclusion, given the theoretical risks and lack of high-quality data, we recommend that the recommendations supported by evidence for anti-TNF therapy should be applied to the non-anti-TNF biologics.

(iii) Studies to date suggest that though biologic therapy does not appear to have a detrimental effect on HCV infection, it should continue to be used only with caution in such patients, following a risk–benefit decision made with a hepatologist (grade 1C, SOA 96%).

There are limited data assessing the effect of immunosuppression on hepatitis C.

Anti-TNF biologics

A prospective RCT of 29 patients receiving ETN, MTX or both found that AST, ALT and HCV viral load did not significantly change across all three arms up to 54 weeks [98]. Three case series totalling 26 patients with IA and chronic HCV treated with either ETN, ABA or INF followed up to 36 months, did not show any significant increase in HCV titre over a 36-month follow-up [99–101]. One patient with both HBV and HCV had breakthrough HCV requiring treatment [99]. Studies to date continue to show that that anti-TNF therapy does not have a detrimental effect on HCV infection. Despite absence of high-quality evidence, in an era of advances in therapeutic options the advice remains to aim for viral control before immunosuppression.

Non-anti-TNF biologics

There is some evidence that the viral load of hepatitis C is increased after RTX treatment compared with anti-TNF therapy, but this was from a small study [96].

There are insufficient data to recommend the use of TCZ, ABA and UST in patients with chronic hepatitis C infection. A systematic review by Campbell *et al*. [34] showed no increased risk of hepatitis C reactivation with TCZ; however, the number of cases was low and further long-term data are required.

In a small observational cohort of four with hepatitis C serology treated with UST, no increase in viral load was seen in patients who had received prophylaxis [97].

HIV

(i) Risk factors for HIV infection should be documented prior to commencing a biologic and, if present, an HIV test should be performed (grade 2C, SOA 97%).

(ii) If considering the use of biologic therapy in HIV positive patients, this should be discussed with an HIV specialist. It should be borne in mind that a reasonable benefit to risk ratio for HIV patients

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

exists with anti-TNF therapy if HIV infection is controlled ($CD4^+$ count >200 cells/mm^3 and viral load undetectable) and anti-TNF is given in combination with highly active anti-retroviral therapy (grade 2C, SOA 99%).

Individuals at risk of HIV are shown in Table 5. There is no evidence base to support the testing of all patients before commencing biologic therapy. The prevalence of HIV in most parts of the UK is low and the likelihood of a positive result in an individual without risk factors is very low. The recent NICE guideline NG60 [102] summarizes the groups in which an HIV test should be offered; it does not advise routine testing in all individuals prior to immunosuppressive agents, unless risk factors are present.

Anti-TNF biologics

The only evidence surrounding the use of anti-TNF therapies for IA in HIV-infected individuals comes from individual case reports and one case series. These reports suggest that they can be used to successfully treat IA in HIV positive patients and are generally well tolerated, provided that HIV treatment is well established prior to anti-TNF therapy initiation and CD4 count is >200 cells/mm^3.

The largest study to date is a retrospective case series of eight American HIV positive patients receiving either ETN, ADA and INF for rheumatic conditions [103]; five patients were receiving concomitant highly active anti-retroviral therapy (HAART). Anti-TNF therapy was restricted to those with CD4 cell count >200 cells/ml and viral loads of $<60\,000$ copies/ml at the initiation of the therapy Over a mean follow-up of 28.1 (range 2.2–55) months, anti-TNF therapy achieved good efficacy with no clinical adverse events attributed to anti-TNF treatment and no deterioration in CD4 count or viral load.

There have also been several individual case reports on the use of anti-TNF agents in HIV positive patients with co-existent rheumatic disease. Most patients receiving concomitant HAART had good clinical outcomes [104–106]; the sole exception is a case report of an HIV patient with PsA in whom ETN had to be stopped due to recurrent infections [107]. Although this patient was receiving HAART, his CD4 count was significantly lower than other cases (<50 cells/mm^3), which may explain the negative outcome.

Non-anti-TNF biologics

There is insufficient evidence to recommend the use of RTX, TCZ, ABA or UST in patients with HIV infection.

Malignancy

(i) Biologic therapies should not be commenced in patients with clinical signs of, or under investigation for, malignancy (basal cell carcinoma excluded) (grade 1C, SOA 96%).

(ii) Patients should be advised that there is no conclusive evidence for an increased risk of solid tumours or lymphoproliferative disease linked with biologic therapy, but that ongoing vigilance is required (grade 1A, SOA 99%).

Anti-TNF biologics: overall malignancy

There has long been concern regarding the possible association between biologic therapies and malignancy, indeed a 2006 meta-analysis of nine randomized controlled trials [108] found a 3-fold increase in the rate of malignancy with INF and ADA. Recent results from several further meta-analyses of both RCTs [26, 109–115] and observational studies [116, 117] have been reassuring and have failed to find a significant association between anti-TNF use and overall malignancy in patients with RA.

Most observational studies using national registry data have also been reassuring; recent studies from BSRBR-RA [118], BIOBADASER [119] and German RABBIT [120] registries have all failed to show a significant association between anti-TNF use in RA and overall malignancy, with up to 52 549 patient-years exposure. In contrast, studies using the Swedish ARTIS [121] and Danish DANBIO [122] registries have reported higher rates of invasive cervical cancer and colon cancer, respectively, in anti-TNF-treated RA individuals compared with those receiving csDMARD. Interestingly in the DANBIO study, when comparing the anti-TNF-treated RA group against the general population this association was no longer seen.

Few studies have looked separately at the AS and PsA anti-TNF-treated population with regard to malignancies. A 2009 meta-analysis of RCTs that included five PsA RCTs and 10 AS RCTs found no significant association [109]. Likewise, a study from BSRBR, which analysed data from

Table 5 Risk factors for HIV infection

Individuals at higher risk for HIV infection
Individuals from a country or group with a high rate of HIV infection
Men who disclose that they have sex with men, or are known to have sex with men, and have not had an HIV test in the previous year
Trans women who have sex with men and have not had an HIV test in the previous year
Individuals who report sexual contact (either abroad or in the UK) with someone from a country with a high rate of HIV
Individuals who disclose high-risk sexual practices
Individuals diagnosed with, or requests testing for, a sexually transmitted infection
Individuals who report a history of injecting drug use
Individuals who disclose that they are the sexual partner of someone known to be HIV positive or of someone at high risk of HIV (e.g. female sexual contacts of men who have sex with men)

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

596 patients with PsA receiving anti-TNF and compared them with RF negative controls (as PsA patients not receiving anti-TNF are not included within this registry) found that the rates of new malignancies were not significantly different between the two groups [123].

Anti-TNF biologics: lymphoma

Patients with RA are known to be at an increased risk of lymphoma compared with the general population independent of treatment; reported risk ratios have varied from 1.9 to 2.7 compared with the general population [124, 125]. As this risk is likely to be highest in those patients with more severe disease, it is important that disease activity is considered as a confounder when assessing any relationship between anti-TNF use and lymphoma in this group. Current data do not suggest that PsA or AS are associated with an inherent increased risk of lymphoma [126–128].

Since the last published guideline in 2009, eight further studies have been identified, including one Cochrane meta-analysis [21], three further RCT meta-analyses [110, 115, 129], one meta-analysis of observational studies [116] and three cohort studies (using the French RATIO [130], Danish DANBIO [122] and Swedish ARTIS [131] registries). Although two of these studies found a higher risk of lymphoma in RA patients receiving anti-TNF agents compared with the general population [130, 131], reassuringly none of them found a significant difference between rates of lymphoma in RA patients receiving anti-TNF therapy compared with control RA patients.

Mariette *et al*. [130], in a cohort study using the French RATIO registry, found no increased risk of lymphoma in SpA patients receiving anti-TNF compared with the general population.

Non-anti-TNF biologics

There is much less long-term observational evidence evaluating the risk of malignancy with the non-anti-TNF biologics; however, findings to date have been reassuring. To date, there have been no safety signals for RTX, TCZ, ABA or UST in malignancy.

Although there is no direct evidence that RTX is safe in malignancy, most long-term data have not shown an increase in risk [13, 33]. Recent data from a pooled case analysis of 1246 patients receiving RTX for >5 years found no increase in the rates of malignancy compared with the general US population or compared with published data in adults with RA [13]. Similarly, data from a French cohort of 186 RA patients who had received at least one infusion of RTX did not show an increased risk of malignancy over 346 patient-years' exposure [mean follow-up 22.3 (15.1) months] [132].

A meta-analysis of 4009 patients exposed to TCZ for a median of 4 years found no significant difference in the incidence of solid and lymphoproliferative malignancies compared with the general population [133].

Solomon *et al*. [134], in a US observational study of 408 patients receiving ABA for RA, found no increased risk of malignancy compared with patients receiving MTX (HR = 1.55, 95% CI: 0.40, 5.97].

In a retrospective analysis of 3117 patients who received UST for up to 5 years, the rate of malignancy (other than non-melanoma skin cancers) was found to be 0.59/100 patients-years (UST 45 mg) and 0.61/100 patient-years (UST 90 mg) [60]. The frequency was found to be no different from the general population.

(iii) There is conflicting evidence regarding the risk of skin cancers with anti-TNF therapy; patients should be advised of the need for preventative skin care, skin surveillance and prompt reporting of new persistent skin lesions (grade 1B, SOA 96%).

Anti-TNF biologics

Although inconsistent, numerous studies have found a positive association between the use of anti-TNF agents in RA and the risk of malignant melanoma (MM). An observational study of US veterans with RA found a higher risk of MM in those exposed to anti-TNF agents compared with those receiving csDMARDs (HR = 1.5, 95% CI: 1.01, 2.24) [135]. An almost identical risk was observed in the Swedish ARTIS registry [136]. Other studies have also noted a positive association between anti-TNF agents and MM, but failed to reach statistical significance; these include the DANBIO registry [122] and a 2011 meta-analysis of observational studies [116]. The largest study to date combined data from 11 European registries including 48 304 RA anti-TNF-treated patients. One hundred and six invasive MM were observed in the anti-TNF group with a pooled standard incidence ratio of 1.2; however, this did not achieve statistical significance (95% CI: 0.99, 1.6; $P = 0.062$) [137]. Higher rates of MM were also observed in the TNF group compared with those receiving csDMARD; however, again statistical significance was not achieved (IRR = 1.14, 95% CI: 0.8, 1.6).

There is also some evidence to suggest that there may be a positive association between anti-TNF use and non-melanoma skin cancer (NMSC). Two RCT meta-analyses of RA patients receiving anti-TNF from 2009 to 2012 failed to find a significant association between anti-TNF use and risk of NMSC, although the more recent and higher quality of the two meta-analyses did observe a non-significant trend towards more NMSC in anti-TNF-treated patients [112, 115]. A further meta-analysis of observational studies found that patients with RA receiving anti-TNF had a 45% higher risk of NMSC compared with csDMARD-treated patients [116]. Recent registry data have also been conflicting; The ARTIS cohort [138] found higher rates of squamous cell skin carcinoma in RA patients treated with anti-TNF therapy compared with those who had not received anti-TNF therapy. While BSRBR-RA [139] and DANBIO [122] registries both observed higher rates of NMSC in anti-TNF-treated RA patients compared with the national population, no difference was observed when compared against RA patients who had not received anti-TNF agents.

Non-anti-TNF biologics

There is less evidence regarding the risk of NMSC in patients receiving non-anti-TNF biologics, but at present

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

there have not been any safety signals to suggest that these drugs increase the risk of NMSC; however, further studies are required.

RTX and ABA were not associated with an increased risk of NMSC in a cohort of 6841 patients with RA receiving biologics in a Medicare cohort [140].

In a long-term safety analysis of 3117 patients with psoriasis receiving UST, the risk of developing NMSC was found to be 0.64 and 0.44/100 patient-years (UST 45 and 90 mg, respectively) [60], a similar rate to the general US population. However, we acknowledge that at a similar time point data in the anti-TNF cohorts were similarly inconclusive. As UST is a relatively new biologic drug, large-scale registry data are currently unavailable. We would therefore recommend that the same precautions outlined for anti-TNF agents be taken for UST.

(iv) Anti-TNF therapy is relatively contraindicated in patients who have had prior treatment with >150 psoralen and ultraviolet A (PUVA) and/or >350 ultraviolet B (UVB) phototherapy. Such patients should be discussed with a dermatologist prior to commencing anti-TNF therapy (grade 2C, SOA 96%).

Patients with a history of psoriasis may be at further increased risk of skin malignancy (in addition to that of anti-TNF therapy) due to previous phototherapy with UVB or PUVA [141].

Anti-TNF biologics

Data directly comparing the rates of skin malignancy in anti-TNF-treated patients with psoriasis who have received phototherapy compared with those who have never received phototherapy are lacking. A recent Dutch study compared rates of NMSC in two cohorts of patients receiving anti-TNF agents for psoriasis (99% of whom had received phototherapy) against a cohort of anti-TNF-treated RA patients [142]. A significantly higher risk of NMSC was found in the psoriasis group (HR = 6.0, 95% CI: 1.6, 22.4) with a shorter time to first NMSC compared with the RA group. A low basal cell carcinoma (BCC) to squamous cell carcinoma (SCC) ratio was also observed suggesting that disease-related factors, such as phototherapy, may be important contributors to the risk of development of NMSC in psoriasis patients treated with anti-TNF. However, the mortality associated with the majority of skin cancers is very low, early detection significantly improves both morbidity and mortality, and most are completely cured with local, predominantly surgical, measures.

Non-anti-TNF biologics

The limited available data from only a few studies do not suggest that any of the non-anti-TNF biologics increase the risk of skin malignancy. We suggest that while prior PUVA or phototherapy exposure is not necessarily a contraindication for this group of drugs, patients should be discussed with a dermatology specialist and treatment decisions made on a case by case basis.

(v) Caution should be exercised in the use of biologics in patients with previous malignancy (grade 1C, SOA 97%). The timing of commencement of biologic therapy post-malignancy is not fixed and will depend on type and stage of malignancy, risk of metastasis and patient views. RTX may be considered as a first-line biologic option in RA patients with previous malignancy (grade 2C, SOA 90%).

There remains a paucity of data concerning the use of biologic therapies in patients with a past history of malignancy. As RCTs have, almost universally, excluded patients with a past history of malignancy, any relevant data have been collected from observational cohort studies. Results from studies published since the last guideline have been reassuring; however, caution should still be advised based on theoretical risk and the fact that patient numbers and further event rates in these studies have generally been low.

Anti-TNF biologics

Of the recent observational cohort studies, BSRBR-RA included the largest number of patients, with 243 RA patients with previous malignancy receiving anti-TNF and 159 receiving csDMARD (1.7% of the BSRBR-RA cohort); the mean interval between malignancy and anti-TNF commencement was long at 11.5 years [143]. Fifty-three new malignancies were identified in this cohort, with no significant difference in the rate of new malignancies between groups. This is in keeping with previous data from the ARTIS [144] and RABBIT [120] registries. Furthermore, a 2016 systematic review observed similar rates of cancer recurrence in anti-TNF-treated individuals (which consisted of patients with RA, psoriasis and IBD) compared with the control csDMARD population (28.8 *vs* 35.1 events/1000 person-years) [145]. Additionally, these rates were also not significantly different from those observed in patients receiving no immunosuppressive therapy.

Two recent studies have looked specifically at the risk of recurrence of NMSC in patients receiving anti-TNF; results from these studies have been conflicting. BSRBR-RA found no increased risk of NMSC recurrence among 177 RA patients with a past history of NMSC receiving anti-TNF treatment compared with DMARD-treated patients, over a median follow-up of 4 years [139]. In contrast, a larger observational study of 6841 RA patients found that anti-TNF use increased the risk of a subsequent NMSC by 49% above that seen in RA patients treated with MTX alone [140].

There is a lack of data regarding the risk of malignancy recurrence in patients with PsA or AS treated with anti-TNF therapy.

Non-anti-TNF biologics

A small study from the BSRBR-RA followed up 23 patients with a prior malignancy who had received RTX as a first biologic for RA. Over a total follow-up time of 81 person-years, no increased rate of further malignancy was observed compared with csDMARD controls (unadjusted HR = 0.45, 95% CI: 0.11, 1.87). Similarly, RTX and ABA

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

were not associated with an increased risk of a second NMSC in a Medicare cohort of 6841 patients with a history of NMSC receiving biologics for RA [140].

Data on the use of TCZ or UST in patients with a history of malignancy are lacking. Due to the theoretical risks, the advice substantiated by evidence for anti-TNF therapies should be applied to patients receiving these therapies.

(vi) The effect of biologics on pre-malignant conditions remains unclear. Caution should be exercised in the use of biologics in such patients. RTX may be considered as a first-line biologic option is these patients (grade 2C, SOA 97%).

Anti-TNF biologics

There is little information concerning the risk of using anti-TNF therapy in patients with pre-malignant conditions. Two studies to date have examined the risk of malignancy in female patients with a past history of cervical dysplasia or carcinoma *in situ* (CIS) of the cervix, treated with anti-TNF. The BSRBR-RA compared 190 RA patients with a past history of CIS of the cervix who were receiving anti-TNF therapy (73% of whom started anti-TNF therapy within 10 years of CIS) against csDMARD controls [146]. Over 893 person-years of follow-up, two new genital cancers were observed in the csDMARD group *vs* no new genital cancers in the anti-TNF group. Due to the low number of new malignant events in the trial, this study was underpowered to draw firm conclusions. Similarly, the DANBIO registry found no new genital malignancies among 208 patients with RA, AS or PsA and a past history of cervical dysplasia or CIS, who had been treated with anti-TNF therapy [147]. Limitations of this study included its relatively short follow-up period of mean 3.5 years for the anti-TNF patients, and the fact that the mean interval between CIS or cervical dysplasia diagnosis and commencement of anti-TNF therapy was 17.7 years. To date, no studies have examined the risk in other pre-malignant conditions such as Barrett's oesophagus or colonic polyps.

Non-anti-TNF biologics

To date, there are no data concerning the use of RTX, ABA, TCZ or UST in pre-malignant conditions. Overall, given the implications of malignancy and the relative lack of safety data in patients with an established or potential malignancy, biologics cannot be recommended at present.

Cardiac problems

(i) Although recent data are reassuring, biologics should be used with caution in patients with class III or IV cardiac failure, working closely with a cardiologist (grade 2C, SOA 96%).

Anti-TNF biologics

TNF-α levels are increased in the general population with heart failure [148] and experimental models have suggested that anti-TNF therapy may improve ventricular dysfunction [149]. However, early clinical trials of ETN and IFX used as a treatment of heart failure reported an increased risk of worsening chronic heart failure [150–152]. As a result the presence of a class III or IV heart failure was a contraindication to the use of anti-TNF therapy in RA (Table 6) [1]. Recently, an observational study compared 8656 patients starting treatment with traditional DMARDs with 11 587 starting an anti-TNF therapy and reported that anti-TNF therapy was not associated with an increased risk of hospital admissions due to cardiac failure compared with traditional csDMARDs [153]. Furthermore, in a recent systematic review and meta-analysis, no significant effect of treatment with TNF inhibitors on CF was observed in RA patients [154]. Interpretation of the results from these studies is hampered by issues relating to potential confounding by indication or contraindication and by lack of control for confounding conditions or severity of RA.

Non-anti-TNF biologics

At present, there are no safety signals to suggest that RTX is associated with deterioration of cardiac function. A pooled case analysis of 1246 patients receiving RTX for >5 years found no difference in cardiac events compared with the general RA population [13].

Studies have shown that IL-6 is associated with exacerbation of ischaemic heart disease and cardiomyopathy [155]. Suzuki *et al*. [156] used i.v. TCZ in a patient with severe RA, with triple vessel coronary artery disease and severely impaired left ventricular function, with no worsening of cardiac function but good results for RA control. There is currently no evidence to suggest that TCZ increases the risk of cardiac failure. However, as with all other biologic clinical trials, patients with moderate to severe heart failure were

Table 6 New York Heart Association classification of heart failure

Class	Patient symptoms
I	No limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnoea (shortness of breath)
II	Slight limitation of physical activity. Comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnoea
III	Marked limitation of physical activity. Comfortable at rest. Less than ordinary activity causes fatigue, palpitation or dyspnoea
IV	Unable to carry on any physical activity without discomfort. Symptoms of heart failure at rest. If any physical activity is undertaken, discomfort increases

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

excluded from the studies and so the risk of biologic therapy in such patients has to be weighed against the potential risk of alternative therapies (such as steroids).

There are no data to suggest that ABA or UST is associated with exacerbation of cardiac failure.

(ii) Biological therapy may be used in patients with previous myocardial infarction or cardiovascular (CV) events (grade 2B, SOA 99%).

Data thus far appear to be reassuring with a potential beneficial effect of anti-TNF therapy on the risk of MI. Recently, a cohort study linking the Swedish National Patient Register and the Swedish Biologics Register [157] compared 7704 RA patients receiving anti-TNF therapy to matched biologic-naïve RA patients at a 3:1 ratio ($n = 23\,112$). There was a significantly lower risk for acute coronary syndrome among RA patients, who were exposed to anti-TNF therapy compared with the biologic naïve patients (HR = 0.82, 95% CI: 0.70, 0.95). This is consistent with the results of a systematic review and meta-analysis that found that anti-TNF therapy in patients with RA was significantly associated with a reduction in the risk of MI [154]. Data from the BSRBR-RA showed no significant difference in the incidence of first MI between RA patients taking TNF inhibitors and csDMARD-treated RA controls [158]. However, the subgroup of anti-TNF-treated patients with a good or moderate EULAR response at 6 months had a lower incidence of MI (3.5/1000 events in responders compared with 9.4/1000 events in non-responders).

Similarly, there appears to be a potential beneficial effect of anti-TNF therapy on CV events but further data are required before firm conclusions can be drawn. Potential confounding by indication or contraindication and by lack of control for confounding conditions or severity of RA should be taken into account, but this would be compatible with the hypothesis that inflammation contributes to development of CV events. In a recent systematic review and meta-analysis, in RA TNF inhibitors were significantly associated with a reduction in the risk of all CV events (risk ratio (RR) = 0.70, 95% CI: 0.54, 0.90), as well as in myocardial infarctions (RR = 0.59, 95% CI: 0.36, 0.97), strokes (RR = 0.57, 95% CI: 0.35, 0.92) and major adverse cardiac events (RR = 0.3, 95% CI: 0.15, 0.57) [154].

There is a lack of data regarding the use of anti-TNF therapy in patients with PsA or AS in patients with previous myocardial infarction or CV events.

Non-anti-TNF biologics

No data exist to suggest that any of the non-anti-TNF biologics increase the risk of myocardial infarction or CV events. In view of the evidence from anti-TNF therapies and a lack of a mechanistic reason, we suggest that the recommendation be applied across biologic therapies.

Respiratory disease

(i) Pre-existing ILD is not a specific contraindication to biologic therapy; however, caution is advised in patients with poor respiratory reserve (in whom a significant drop in lung function would be potentially life threatening); in this situation it is advised to work closely with a respiratory physician with a specialist interest in ILD (grade 2C, SOA 99%).

(ii) RTX or ABA may be considered a first-line biologic in patients with ILD (grade 2C, SOA 84%).

ILD is a common manifestation in patients with RA (prevalence 10–30%) and is generally associated with more severe disease [159, 160]. Uncertainty remains surrounding the natural history of RA-ILD and the effects of biologics (and csDMARDs) on this disease. Predominantly studies are centred on RA-ILD although there are pulmonary manifestations associated with other forms of IA, such as a prevalence of 0–30% for lung involvement in AS patients, most commonly upper lobe fibrosis.

Anti-TNF biologics

Since the 2010 guideline there have been several observational retrospective cohort studies assessing the relationship between ILD and anti-TNF therapy. The BSRBR-RA found no significant increase in mortality in 356 patients with RA-ILD treated with ETN, ADA or IFX, compared with those receiving csDMARD alone [161]. Selection bias could be an explanation for these results as this could have led to increased mortality in the traditional DMARD group and a favourable reduction in the mortality rate ratio for biologics use. The conclusion was that UK physicians were appropriately selecting patients suitable for anti-TNF therapy when underlying ILD was present.

Where there is no pre-existing ILD, a US study found that anti-TNF therapy was not associated with a diagnosis of ILD among patients with RA over a mean follow-up of 3 years [162]; comparisons across anti-TNF agents found no differences in risk. The number of cases was limited in this study, with only 38 new ILD cases (23 on anti-TNF) among the 8417 persons included (0.4%).

In terms of selection of patients, univariate analysis in a small Korean study suggested age at initiation of anti-TNF therapy was a risk factor for death when looking at a population of 24 RA-ILD patients on anti-TNF (76 *vs* 64 years old, $P = 0.043$) [163]. A Japanese study [164] found that over 1 year of follow-up of 58 RA patients with pre-existing ILD, 14 had ILD events and that the proportion was greater than the comparator arm without pre-existing ILD (24 *vs* 3%, $P < 0.001$).

Pre-existing lung disease should not be considered an absolute contraindication to an anti-TNF. However, in patients with poor respiratory reserve (in whom a significant drop in lung function would be potentially life threatening), caution should be exercised when choosing an anti-TNF. Decisions should be made on an individualized basis in conjunction with a respiratory physician, and with full appreciation of the limited evidence base.

Non-anti-TNF biologics

There is little evidence on the impact of RTX, ABA, TCZ and UST on the occurrence or exacerbation of ILD, and this is often limited to case reports.

A 2014 systematic review of case reports and series (from 1975 to 2013) of biologics causing ILD or worsening

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

pre-existing ILD in RA patients found eight case reports for TCZ, three for RTX and one for ABA [165].

A US database study of 11 219 RA patients [166] found the lowest IR of ILD occurrence was with ABA (IR = 4.0/1000 person-years, 95% CI: 1.6, 8.2/1000 person-years); the highest being with INF (IR = 12.2/1000 person-years, 95% CI: 5.6, 23.2/1000 person-years); however, no significant differences in the incidence of ILD was found between the different biologic classes. No studies to date have examined the relationship between UST and ILD in PsA.

Until further data are available concerning any causal relationship between non-anti-TNF biologics and ILD, we suggest that recommendations given for anti-TNF therapies should be followed. There is a weak evidence base to suggest that ABA and RTX might have less effect on ILD than other biologics [165–167].

Uveitis

(i) ADA and INF can be considered for the treatment of uveitis, in preference to ETN, which appears to be associated with lower rates of treatment success and has been associated with the development of uveitis. The relative risks of these agents should be taken into account when selecting which treatment to use (grade 1 C, SOA 96%).

Anti-TNF biologics

A systematic review by Levy [168, 169] concluded that ADA and INF can be considered as second-line immunomodulatory agents for the treatment of severe ocular inflammatory conditions including posterior uveitis, panuveitis, severe uveitis associated with seronegative spondyloarthropathy and scleritis in patients requiring immunomodulation who have failed or who are not candidates for antimetabolite or calcineurin inhibitor immunomodulation. INF and ADA can be considered in these patients in preference to ETN, which appears to be associated with lower rates of treatment success. At present, ADA is the only anti-TNF agent licensed by the European Medicines Agency for the treatment of uveitis.

While ADA and INF [168, 169] have successfully treated uveitis, there are several case reports of uveitis developing in patients treated with ETN [170, 171]. A registry-based study by Lim *et al*. [172] reported 43 cases of uveitis in patients who were receiving anti-TNF treatment over a period of 8 years. The number of patients taking ETN, INF or ADA in this group was 20, four and two, respectively; ETN therapy was associated with a significantly greater number of reported uveitis cases in comparison with INF ($P < 0.001$). This study was, however, limited by the information on the clinical diagnoses available to the authors.

More data are required on uveitis associated with each of the anti-TNF agents before further conclusions can be drawn on the risks associated with these agents.

Non-anti-TNF biologics

There is a paucity of data concerning the safety of non-anti-TNF biologics in patients with a history of uveitis. There is one case report of a patient with RA treated with TCZ who developed acute anterior uveitis 5 weeks after stopping the therapy; however, causality is difficult to establish in this scenario [173]. Aside from that, there have not been any safety signals to suggest that there is concern about using these drugs in this patient cohort.

There is some, mostly observational, data to suggest that non-anti-TNF biologics can successfully treat patients with refractory uveitis. A systematic review by Simonini *et al*. identified nine articles reporting data on the use of non-anti-TNF biologics to treat refractory uveitis (six retrospective chart reviews, two case series and one single-blind RCT of 16 patients) [174]. ABA, TOC and RTX all demonstrated efficacy in selected categories of chronic uveitis, refractory to previous DMARDs and anti-TNF agents; further randomized clinical trials in this area are needed.

Demyelinating disease

(i) Anti-TNF therapy should not be given when there is a personal history of multiple sclerosis or other demyelinating diseases. Consider using a non-anti-TNF biologic in this situation (grade 2B, SOA 97%).

Anti-TNF biologics

Studies have suggested an aetiological role for anti-TNF therapies in the development of neurological disorders; the disease is temporally associated with initiation of therapy, the symptomatology is suggestive of an antigen-mediated hypersensitivity process, and the disease improves or resolves after discontinuation of therapy and a positive rechallenge phenomenon is observed [175, 176].

Multiple sclerosis

TNF blockade was shown to cause worsening of demyelinating disease in early studies of an anti-TNF therapy, in which patients with active multiple sclerosis (MS) documented an increase in MS flares on this therapy [177]. The prevalence of demyelinating disease induced by biologic therapies, reported in RCTs and post-marketing studies, has been estimated to range from 0.02 to 0.2% [178]. In a Canadian database of 105 000 RA patients there was a trend towards around a 30% increase in demyelinating events after exposure to anti-TNF agents, but this was not statistically significant [179]. A Danish registry study of almost 28 000 patients with IA found a significantly increased standardized incidence ratio of MS in men with RA or AS treated with anti-TNF therapy (SIR = 3.48, 95% CI: 1.45, 8.37), but not in women [180].

Optic neuritis

Case reports of patients developing optic neuritis during anti-TNF treatment exist. A pooled case report study detailed 15 patients who developed optic neuritis while on anti-TNF therapy; eight of these patients had received IFX, five ETN and two ADA [181]. On stopping anti-TNF treatment, seven patients experienced either partial or complete resolution of their symptoms while four patients continued to have symptoms. Recently there has been a USA-based study of 61 000 individuals with inflammatory disease and new anti-TNF or non-biologic DMARD use.

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

Among this cohort, three optic neuritis cases (two with IFX and one with ETN) were detected among anti-TNF new users, providing a crude IR of 10.4 (95% CI: 3.3, 32.2) cases per 100 000 person-years. No cases occurred in the csDMARD comparison group. However, in a secondary analysis of current and past users of csDMARDs and anti-TNF, optic neuritis rates were similar in the anti-TNF and comparison groups, respectively, leading the authors to conclude that anti-TNF therapy does not appear to promote the development of optic neuritis in patients who lacked a prior documented history of optic neuritis [182].

Demyelinating peripheral nervous system disease

The association between anti-TNF treatment and various disorders of peripheral nerves such as Guillain–Barré syndrome, chronic inflammatory demyelinating polyneuropathy and mononeuropathy multiplex has been highlighted in various case series and case reports [183]. Cases were reported for all three first generation anti-TNF agents with symptoms developing over a wide range of time intervals from starting anti-TNF treatment (8 h to 2 years) and lasting for varying time periods from 3 weeks to 35 months. Withdrawal of anti-TNF resulted in slow resolution of symptoms in many cases; however, additional treatment was required for others. A small minority of patients, however, never achieved symptom resolution.

Prognosis following demyelinating disease or peripheral neuropathy

In the BIOGEAS registry, 30% of patients with demyelinating disease ($n = 44$) had no resolution of symptoms. Eleven per cent of peripheral neuropathies had no resolution of symptoms on stopping therapy [175, 178]. Similarly, in a French registry, 22% of patients developing CNS demyelination on biologics went on to develop MS despite cessation of biologic therapy [184].

In light of these findings, individuals with a personal history of multiple sclerosis or other demyelinating diseases should not start anti-TNF therapy.

Non-anti-TNF biologics

There is no evidence to suggest that RTX, ABA or UST increases the risk of demyelinating diseases. Likewise, there is no consistent evidence to argue against the use of TCZ in demyelinating diseases; indeed there is ongoing interest in its use for the treatment of certain autoimmune neurological disorders such as neuromyelitis optica spectrum disorder [185]. Sato *et al*. [186] used TCZ in treating RA in a patient with multiple sclerosis for 5 years with no progression of her MS.

In view of the above evidence, we suggest that a non-anti-TNF biologic is used in preference to anti-TNF therapy in patients with a personal history of demyelinating disorder.

Diverticular disease

(i) Exercise caution with TCZ in patients with diverticular disease, particularly when using concurrent NSAIDs and/or steroids (grade 2C, SOA 98%).

Gastrointestinal perforation has been reported in patients treated with TCZ for RA. An occurrence of 2.8/1000 person-years was reported by Schiff *et al*. [187] in a pooled meta-analysis of five RCTs and two long-term extension studies, compared with 2.0/1000 person-years reported in the control group. Diverticulitis was present in 16 of the 18 patients who had a gastrointestinal (GI) perforation while receiving TCZ; most patients had also been treated with NSAIDs and/or steroids.

A systematic review by Gout *et al*. [188] found that the risk of GI perforation with TCZ was lower than the risk with steroid and NSAID use, but higher than with anti-TNF therapy.

A large study by Curtis *et al*. [189] looking at administrative data from a large US health plan showed that there was no increased risk of GI perforation with the use of non-TCZ biologics or MTX, but there was an increased risk with concomitant use of steroids and NSAIDs. The factor leading to the highest increase in risk was previous diverticulitis.

Vaccinations

(Also refer to vaccination recommendations while on biologic therapy).

(i) HBV immunization should be considered for at risk patients (grade 2C, SOA 94%).

Individuals with ongoing risk factors for hepatitis B infection [as outlined in recommendation (i) for active TB] should undergo immunization prior to starting anti-TNF treatment. Hepatitis B vaccines are inactivated vaccines and therefore do not contain live organisms and cannot cause hepatitis B in an immunosuppressed individual. There are limited data with regard to response to hepatitis B immunization in patients with rheumatic disease receiving biologic therapy. There is circumstantial evidence indicating that TNF blockade may directly modulate humoral responses [190], with one study suggesting that TNF blockade with ETN decreases responses to the hepatitis B vaccine; patients with RA who were treated with MTX had very good response rates, whereas those treated with an MTX–ETN combination or ETN alone had poor response rates [191]. Therefore, though it is safe to give hepatitis B vaccine to a patient on anti-TNF treatment, if possible, the first hepatitis B vaccine should be given prior to commencing anti-TNF therapy.

Due to the risk of poor response, it is important that immunization against hepatitis B does not encourage relaxation of other measures to prevent exposure to the virus, such as condom use and needle exchange [192].

(ii) Patients >50 years should undergo vaccination against herpes zoster (HZ) assuming there are no contraindications (e.g. treatment within the past 3 months with >40 mg prednisolone per day for >1 week, >20 mg prednisolone per day for >14 days, MTX >25 mg/week, AZA >3.0 mg/kg/day). This should be administered preferably >14 days before starting biologic therapy (grade 2C, SOA 97%).

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

The risk and severity of shingles (HZ infection) is considerably higher among immunosuppressed individuals, with evidence suggesting that people with rheumatic diseases have around double the incidence of shingles of the general population [193, 194]. A 2014 meta-analysis including ACR, EULAR and BSR registry data found that the pooled risk ratio for HZ in patients with IA on anti-TNF agents was 1.61 (95% CI: 1.16, 2.23). The proportions of severe HZ ranged from 2.0 to 5.5% with csDMARDS, compared with 4.9–20.9% with TNF-blockers [195].

According to Public Health England recommendations, eligible individuals anticipating immunosuppressive therapy should ideally be assessed for vaccine eligibility before starting treatment that may contra-indicate future vaccination [196]. Eligible individuals who have not received Zostavax should receive a single dose of vaccine at the earliest opportunity and at least 14 days before starting immunosuppressive therapy.

HZ vaccine is now recommended in the UK for all individuals aged 70–79 and a national vaccination programme is underway. Zostavax reduces the risk of shingles by ~50% in immunocompetent adults aged ⩾60 years [197]. Efficacy of the vaccine appears to wane within the years after vaccination, with studies suggesting efficacy of 39.6% for prevention of HZ and 60.1% for prevention of postherpetic neuralgia 4–7 years post-vaccination [198]. It is licensed for the use in individuals aged ⩾50 years, and therefore could not be recommended for patients younger than this [199].

Vaccination has been shown to be associated with reduced incidence of HZ in a study of over 460 000 patients aged ⩾60 years with autoimmune diseases [200]. As HZ vaccine is a live attenuated vaccine, it carries a small risk of infection, particularly in immunosuppressed individuals. However, in this study, among 633 patients with recent or current exposure to biologics at the time of vaccination, no case of HZ or varicella occurred. These data were, however, extracted from administrative claims from hospitals and cases of HZ and varicella were not confirmed with medical records review. Encouragingly, in two further studies, no increased incidence of HZ or varicella zoster was shown following vaccination in individuals with autoimmune disease receiving a variety of biologic therapies [201]. Nonetheless, Public Health England currently recommends that HZ vaccine should not be given to individuals already on biologic therapy or who, in the past three months have received >40 mg prednisolone per day for >1 week, >20 mg prednisolone per day for >14 days, non-biological oral immune modulating drugs (e.g. MTX >25 mg/week, AZA >3.0 mg/kg/day) [196, 202].

(iii) Patients who do not have a positive history of varicella zoster (chickenpox) infection should have a varicella zoster virus antibody test. If this is negative, and there are no contraindications (as listed in (ii)) varicella zoster vaccination should be offered prior to biologic commencement (grade 2C, SOA 98%).

Varicella zoster virus, which causes chickenpox, is more common and serious in immunosuppressed individuals, as they are at risk of severe and potentially fatal disseminated varicella infections [203, 204]. It is the most frequent viral opportunistic infection (OI) seen in patients on MTX or anti-TNF agents [23].

The varicella vaccine is a live attenuated vaccine, and the two-dose vaccination schedule provides around 75% protection in adolescents and adults—mild breakthrough infections can occur in around 10% of adults [205]. For this reason it is not recommended for those already on immunosuppressive medication, such as AZA (>3.0 mg/kg/day), ciclosporin, MTX (>25 mg/week), CYC, LEF or equivalent 40 mg prednisolone/day); this group will cover a significant proportion of patients due to start anti-TNF therapy.

In individuals due to start biologic therapy who are not in the above category, varicella zoster vaccination is recommended, in addition to vaccination of healthy susceptible close household contacts of immunocompromised patients (e.g. children of a patient due to start biologic therapy who have not had varicella zoster). Patients without a definite history of varicella zoster virus infection should undergo a varicella virus antibody test. If negative, and there is no contraindication, they should be offered vaccination on the two-dose schedule. Personal recall of varicella infection has been shown to be a good predictor of serological immunity [206, 207].

For patients receiving biologic therapy

Monitoring on treatment

(i) All patients should be reviewed for drug safety in a specialist department at least every 6 months. High risk patients (e.g. those at high risk of TB) should be reviewed every 3 months (grade 2C, SOA 94%).

There is no evidence on the optimal monitoring requirements for patients receiving biologics. However, in view of the aforementioned potential risks associated with these treatments, and the NICE requirements to ensure a satisfactory clinical response to treatment, we suggest that patients are reviewed at least every 6 months by a rheumatology specialist. Higher risk patients may require more frequent review, as supported by NICE guidance. The 2011 NICE guideline cg117 [76] and the 2005 BTS guideline [208] recommend that high-risk TB patients should be monitored every 3 months (with a CXR and sputum cultures, if respiratory symptoms develop).

(ii) Patients prescribed a biologic (other than TCZ) without concomitant csDMARD (or with csDMARDs that do not require blood test monitoring), should have monitoring blood tests (FBC, creatinine/calculated GFR, ALT and/or AST and albumin every 3–6 months (grade 2C, SOA 97%).

Anti-TNF biologics

Haematological abnormalities have been reported in patients treated with anti-TNF agents but in many cases

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

there have been other co-prescribed medications that may have been responsible for these changes. One case series reported neutropaenia ($<2.0 \times 10^9$/l) in 14.3% of 133 RA patients on anti-TNF therapy [209]. A history of previous neutropaenia on csDMARD therapy and a low baseline neutrophil count were shown to be predictors of neutropaenia. Two other studies have reported rates of anti-TNF-induced neutropaenia of 8 and 14% [210, 211]. The majority of reported cases of anti-TNF-induced neutropaenia were mild, did not result in any significant clinical complications and did not require modification in anti-TNF therapy. Reports of anti-TNF-associated pancytopenia and aplastic anaemia are rare but in some cases have been fatal [212].

More recently, a US cohort of 1322 patients receiving anti-TNF therapy had no increase in prevalence of anaemia, leucopenia or thrombocytopenia [213]. Other studies have shown resolution of anaemia of inflammation following treatment with anti-TNF agents. Niccoli *et al*. [214] monitored the FBC of 106 patients with AS over a 6-month period and found Hb, MCV, iron, ferritin, CRP and ESR improved, reaching statistical significance. However, this study is confounded by the simultaneous stopping of NSAIDs on commencement of anti-TNF, perhaps leading to a reduction in insidious GI bleeding.

Liver function test derangement has also, albeit rarely, been associated with anti-TNF therapy. In an observational study of 6861 RA patients, over 6.5 years of follow-up, elevations in AST and ALT were found in 6.67% of patients [215]; however, only 0.77% had levels more than twice the upper limit of normal. IFX (as opposed to ADA or ETN) was associated with the highest frequency of elevations.

Anti-TNF therapy is not known to affect renal function [216]; however, IA is associated with chronic kidney disease [217]. Hence in individuals already undergoing blood monitoring, an assessment of renal function may be useful to detect any deterioration in renal function and enable early investigation and treatment that may prevent further decline.

Thus, in light of reports of pancytopenia and liver function test elevation with anti-TNF therapy, it is recommended that patients undergo blood monitoring on a regular basis (every 3–6 months).

Non-anti-TNF biologics

Late-onset neutropaenia is a recognized side effect of RTX therapy and, although it usually follows a benign course and is infrequent, can present with infection [214, 215]. A UK study of 108 patients receiving RTX for RA between October 2007 and July 2011 identified five patients (4.6%) who developed late-onset neutropaenia (LON; neutrophil count $\leqslant 1.5 \times 10^9$ after a median of 151 days [70–181, 215]; two patients developed pneumonia. A similar rate of 6% (eight patients) was observed in a Norwegian single-centre case review analysis of 133 RA patients, and was more common in those with low IgM and IgG levels [12]. Fifty per cent of patients with LON had infection at the onset of neutropaenia; six patients were rechallenged with RTX without recurrence of LON. In this study it took a median of 6.5 days for recovery of LON.

(iii) Patients receiving csDMARD may require more regular laboratory monitoring (as per BSR/BHPR non-biologic DMARD guidelines, 2017) (grade 2B, SOA 96%).

Patients receiving biologic therapy alongside a csDMARD may require blood test monitoring more frequently than every 3 months, depending on which csDMARD they are receiving. Minimal monitoring requirements for the different csDMARDs and the blood results that require action are given in the 2017 BSR/BHBR non-biologics DMARD guidelines [5]. The blood results that require action are the same as those defined in the BSR 2017 csDMARD guideline [5].

(iv) Patients receiving RTX should have serum immunoglobulins (especially IgG and IgM) checked prior to each cycle of RTX. Clinicians and patients should be aware that the risk of infection increases as serum IgG levels fall below normal. Lower dose RTX may be considered in this situation (grade 2A, SOA 99%).

Lower levels of IgG have been associated with an increased risk of infection in individuals receiving RTX [13]. Van Vollenhoven *et al*. [13] monitored Ig levels every 8–16 weeks in patients with RA receiving RTX and found that following RTX therapy $\leqslant 3.9\%$ had low IgA or total Ig levels at any time, while 14.8 and 37.9% had below normal IgG and IgM levels, respectively, any time. Over the first 5 years of treatment the proportion of patients with IgM but not IgG or IgA below the lower limit of normal continued to increase. Serious infection rates in those patients who developed low IgG levels were higher than the serious infection rates in patients who never developed low IgG; however, this study was limited by low numbers in the low IgG subgroup (143 patients).

Although there is no evidence to suggest an absolute total Ig, IgM or IgG threshold where RTX should not be given, clinicians and patients should be aware that the risk of serious infection increases as serum IgG level falls. Lower dose RTX (such as 2×500 mg infusions) may be considered in this situation [13, 218].

(v) Patients receiving i.v. or s.c. TCZ, with or without MTX, should have laboratory monitoring every 4 weeks for neutrophils and ALT/AST (grade 2B). Blood tests should ideally be in the week before i.v. TCZ, and in the 3 days before every fourth s.c. injection. Any decision to halt treatment should be made in accordance with the guidance in the TCZ SPC (grade 2C, SOA 96%).

TCZ has been found to cause a reduction in absolute neutrophil count (ANC) in a number of studies [219–221]. This is thought to be due to peripheral margination of neutrophils, but is not associated with an increased frequency of infection. Nishimoto *et al.* [220] found that 6% of patients on TCZ experienced neutropaenia grade 3 or 4, with a further 15% having grade 1 or 2. Interestingly, these events were not associated with infection. Nakamura *et al*. [219] found ANC to drop in the first 24 h after i.v. TCZ administration, but the ANC recovered by the next

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

infusion 4 weeks later. Maini *et al*. [221] found ANC to reach a nadir at 2 weeks post-infusion, with recovery occurring within the following 2 weeks.

More recently, a double blind, double dummy RCT [222] compared patients receiving TCZ *vs* MTX *vs* TCZ + MTX. No significant difference was seen between the groups in terms of infection or drop in ANC. A 97-week open label extension of a 24-week double blind study comparing i.v. and s.c. formulations of TCZ has shown that even at 97 weeks, a small number of patients still develop new grade 3 or 4 neutropaenia, with numbers similar in both i.v. and s.c. groups (0.81 and 0.76%, respectively) [223].

Rises in transaminases (ALT and AST) have been found with TCZ in a number of studies. Various studies have noted raised transaminases that spontaneously resolved without the need for TCZ dose change [224–228]. Dougados *et al*. [229], and others, found that 41–51% of patients on TCZ in combination with a conventional DMARD will have spontaneously resolving episodes of raised ALT up to three times the upper limit of normal [224, 225, 228, 229]. In a retrospective cohort study looking back over 45 months, Machado-Alba *et al*. [230] found 5/51 (9.8%) patients on TCZ developed a rise in ALT up to three times the upper limit of normal.

The TCZ SPC has detailed guidance concerning when to stop or change therapy in the context of blood test abnormalities and should be referred to (http://www.medicines.org.uk/emc/medicine/22311/-SPC/RoActemra).

(vi) Patients receiving TCZ should have their serum lipids checked at 3 months, and treated appropriately if abnormal; they may be checked again thereafter at physician's discretion (grade 2A, SOA 99%).

TCZ has been noted to cause an initial rise in serum lipids [187, 221, 231], but long-term extension studies have shown them to broadly stabilize within 3 months [232]. A *post hoc* analysis by Gabay *et al*. [233] of 324 patients in the ADACTA trial up to 24 weeks showed that compared with ADA, TCZ was associated with a slightly raised LDL cholesterol level, but the overall lipid profiles were similar. An increase in cardiac events has not been found, perhaps with the deleterious effect of higher lipids being offset by better control of inflammatory disease. Further work is required in this area.

Co-morbidity management on treatment

(i) Patients with significant co-morbidities who are also receiving biologic therapies, should have close involvement with specialists in that field (grade 1C, SOA 99%).

Infection

In general:

(i) All biologics should be discontinued in the presence of serious infection, but can be recommenced once the infection has resolved (grade 1A, SOA 99%).

Anti-TNF biologics

No studies to date have assessed outcomes in patients with IA receiving anti-TNF therapy who did not stop treatment in the presence of severe infection; however, there are data, primarily from case reports, suggesting that infections may become more severe if patients continue with anti-TNF therapy [234]. Patients should be made aware of the increased risk of infection, and should be advised to stop therapy until the infection has resolved.

Non-anti-TNF biologics

As no studies have investigated the outcome in patients continuing with these drugs in the presence of active infection, caution is advised and it is suggested that non-anti-TNF biologics should also be stopped until infection has cleared. Further data in this area are required.

Mycobacterium tuberculosis

(i) Patients commenced on biologics should be closely monitored for TB while on treatment and for at least 6 months after stopping treatment (grade 2C, SOA 98%).

This recommendation is largely based on expert opinion from NICE [76] and the BTS guidelines [208]. Any patient who develops symptoms consistent with TB, even if their pre-biologic TB screening was negative, should be investigated for active TB, initially with a chest X-ray and sputum examination.

Up to a 19% risk of TB reactivation has been reported; however, this varies according to the local rates of a positive TST/IGRA and the local incidence of TB. Most cases of reactivation have occurred during the first year of anti-TNF treatment after completion of chemoprophylaxis [235].

(ii) Patients on biologics who develop symptoms suggestive of TB should receive full anti-TB treatment but may continue with their biologic if clinically indicated after risk/benefit analysis (grade 2C, SOA 96%).

Patients who develop active TB while on biologic treatment should receive full anti-TB chemotherapy [236]. In these circumstances, treatment can be continued if clinically indicated because the patient would otherwise be prevented from receiving the continued clinical benefit to their underlying disease and may have a flare up or major clinical deterioration.

While there is limited evidence in this area, it is reported that HIV positive individuals with reduced CD4 counts and clinical TB, who are even more immunosuppressed than those on anti-TNF treatment, respond equally well to TB treatment as those who are HIV negative [237].

Opportunistic infection

(i) Health-care professionals should have a high index of suspicion for atypical/OIs, especially if current or recent steroid use. Biologic therapy should be

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

promptly stopped in suspected cases. Patients should have rapid access to specialist health care for consideration of early treatment (grade 1B, SOA 99%).

Anti-TNF biologics

There have been a few observational cohort studies investigating the association between OIs and anti-TNF use. The largest of these studies, the US Safety Assessment of Biologic Therapy project, found a higher incidence of non-viral OIs compared with patients initiating non-biologic DMARDS [238]. Within the cohort of 33 324 new anti-TNF users over a 9 year period, 80 non-viral OIs were identified with pneumocystosis being the most common, accounting for 20% of OI cases ($n = 16$); histoplasmosis ($n = 9$) and cryptococcus ($n = 3$) were the next most frequently observed fungal OI. Nocardiosis ($n = 12$) had the highest incidence for opportunistic bacterial infection ($n = 12$), followed by salmonellosis [8] and listeriosis ($n = 4$). The overall crude rate of non-viral OI in the TNF group was 2.7 *vs* 1.7 per 1000 person-years in those receiving only csDMARD (adjusted HR = 1.6, 95% CI: 1, 2.6).

Data collected from the US CORONNA registry found that anti-TNF drugs were an independent predictor of OI (bacterial and viral) [23]. One hundred and sixty-four OIs were observed in the TNF-treated group, with an IRR of 1.18 (95% CI: 1.08, 1.32) compared with MTX alone. The combination of MTX and anti-TNF did not appear to further increase the risk of OI above that of anti-TNF alone. In both studies, baseline steroid use was an independent risk factor for OI; however, to date there is insufficient evidence to support the use of primary prophylaxis in this group.

Non-anti-TNF biologics

The risk of non-TB atypical OIs does not seem to be increased with RTX, TCZ, ABA or TCZ compared with other biologics, but long-term data are lacking [59].

Vallabhaneni *et al*. [239] looked at 4000 patients who had received TCZ, and 11 of these (0.28%) developed invasive fungal infections, which is non-inferior to other biologics. There are no observational data regarding the long-term risk of UST and atypical OI.

(ii) In patients exposed to primary varicella through a close household contact [and without a positive history of varicella zoster (chickenpox) infection or vaccination], post-exposure prophylaxis with varicella zoster immune globulin should be considered if the risks from infection are perceived to be significant. Shingles should be treated conventionally (grade 2C, SOA 94%).

Anti-TNF biologics

Several studies have found a significant association between anti-TNF therapy and risk of HZ. The most recent data comes from the Australian ARAD database of 2157 RA patients [42]. RA patients receiving IFX, ETN or ADA had a 37% higher risk of shingles (adjusted hazard ratio (aHR) 1.37, 95% CI: 1, 2.92) compared with csDMARD users. Data from BSRBR-RA showed that patients receiving first generation anti-TNF were found to have an up to 80% higher risk of shingles (aHR = 1.8, 95% CI: 1.2, 2.8; crude incidence of 1.6/100 person-years) [240]. This study, along with data from the RABBIT, BIOBADASER and CORRONA registries, was included in a 2014 meta-analysis, which found a pooled risk ratio for HZ with TNF inhibitors of 1.61 (95% CI: 1.16, 2.23) [195].

Relatively fewer studies have focused on varicella zoster (chickenpox) risk and anti-TNF therapy. Higher rates of hospitalized chickenpox and shingles compared with the general population have been observed in a study combining the BIOBADASER registry with the Spanish national hospital discharge database [241]. The IR for hospitalized shingles and chickenpox in patients receiving anti-TNF therapy was 44 and 26 per 100 000 person-years, compared with an expected IR of 3.4 and 1.9 per 100 000 person-years, respectively, in the general population.

There remains little evidence on the effectiveness of varicella zoster immune globulin (VZIG) in preventing infection in immunosuppressed patients. A study of 81 immunosuppressed children who received VZIG following household exposure to varicella, found a moderate response to VZIG, although 49 children still developed varicella infection, including some who had serological evidence of past exposure [242]. Until more data are available, we feel that it is appropriate to recommend that VZIG is considered as a post-exposure prophylaxis for patients receiving biologic therapies who are exposed to varicella infection in whom the risks of infection are perceived to be high. VZIG is an intramuscular injection, and should be given as soon as possible—not later than 10 days after exposure; a second dose should be given if further exposure occurs >3 weeks after the first dose.

Non-anti-TNF biologics

There have been reports of higher than expected episodes of HZ in patients receiving RTX and ABA from cohort studies [35, 243]. Data are lacking on the risk of TCZ and UST and HZ. Until more data are available, we suggest that the recommendations for anti-TNF therapies be applied to all biologics.

(iii) Clinicians should be vigilant for progressive multifocal leukoencephalopathy (PML), which has been primarily associated with RTX but has also been reported with anti-TNF therapy. Treatment should be stopped if PML develops. Rechallenge is not recommended (grade 1C, SOA 99%).

PML has been reported in a few more patients than was reported on the previous guideline and to date there have been 11 cases in patients with RA [244]. The majority of case have been in association with RTX use, but rarely cases have been reported with other agents [245]. Considering how many more patients have been treated with RTX since the last guideline, this should be

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

reassuring of the lack a major signal, but vigilance should still be maintained.

The prognosis for PML is poor, with a high level of mortality at 1 year. Although there is no treatment for PML, stopping biologic therapy may slow progression. There are no data regarding PML receiving biologic therapies for non-RA IA. No cases of PML have been reported with TCZ, ABA or UST.

Hepatitis B and C infection

(i) Close monitoring of serum amino-transaminases and HBV DNA load is recommended in patients with occult or overt HBV infection treated with biologic therapy (grade 1C SOA 99%).

Patients should be followed carefully by means of ALT and HBV DNA testing and treated with anti-viral therapy upon confirmation of HBV reactivation before ALT elevation. The frequency of monitoring can range from 1 to 3 months depending on the type of immunosuppressive therapy and comorbidities [93].

(ii) Close monitoring of serum amino-transaminases and HCV RNA during therapy should be considered in patients with HCV treated with a biologic (grade 1C, SOA 99%).

Studies to date continue to show that biologic (especially anti-TNF) therapies do not have a detrimental effect on HCV infection [99, 101], but it would be prudent to work closely with a hepatologist and arrange monitoring.

(iii) Patients with serological evidence of occult HBV infection may require concomitant anti-viral treatment if detrimental changes in monitoring tests develop (grade 1B, SOA 99%).

Patients with previous occult HBV infection treated with biologic therapy who reactivate their HBV have generally good outcomes even if anti-viral treatment was required [90, 92, 246]. In these studies anti-viral treatment was generally given if HBV DNA level was $>10^5$ IU/ml, although we recommend that thresholds of treatment should be decided working with a hepatologist given that European Association for the Study of the Liver guidelines recommend treatment based on a combination of raised ALT, HBV DNA level >2000 IU/ml and severity of liver disease [93].

HIV

(i) Patients with HIV receiving anti-TNF therapy require close monitoring of viral load and CD4 count. Treatment changes should be made in light of results, with guidance from an HIV specialist (grade 2C, SOA 99%).

Refer to the earlier section on HIV.

Malignancy

(i) Patients should be encouraged to comply with national cancer screening programmes (grade 1C, SOA 99%).

(ii) Patients should be investigated for potential malignancy if clinically suspected and biologics should be stopped if non-BCC malignancy is confirmed (grade 1C, SOA 97%).

There is an absence of evidence regarding the cessation of biologic therapy in the presence of proven malignancy; certainly no studies to date have investigated whether continuing or stopping biologic therapy in this situation has any effect on prognosis. Until any further evidence is available, it is suggested that all biologic therapies should be stopped if malignancy (excluding skin BCC) is confirmed, and any ongoing future treatment discussed with oncology specialists on a case by case basis.

(iii) Biologic therapies may be continued in patients who develop a BCC that is fully excised, after careful discussion with the patient and a risk–benefit analysis (grade 2C, SOA 97%).

There have been no studies to date assessing the outcome of biologic-treated patients who undergo complete excision of a NMSC and continue with biologic therapy. As described earlier, there is evidence to suggest that anti-TNF agents increase the risk of a future NMSC in individuals who have a past history of them [140], but conflicting results have also been reported in other studies [140]. Due to the low inherent risk of metastasis following the complete excision of a BCC, we suggest that in this situation biologic therapies may be continued after careful discussion with the patient and possible input from a dermatology specialist.

Cardiac problems

(i) If patients develop worsening cardiac failure while on anti-TNF, consideration should be given to stopping therapy if no other explanation for worsening cardiac failure is found following input from a cardiologist (grade 2C, SOA 99%).

Although recent studies have reassuringly not found a significant effect of TNF inhibitors on cardiac failure [153, 154], early clinical trials did report a detrimental association [150–152]. There are numerous causes of cardiac failure including ischaemic heart disease, hypertension and valvular heart disease, all of which are more common than drug-induced causes. With this in mind, we suggest that consideration is given to stopping anti-TNF agents in individuals with worsening cardiac failure if this cannot be attributed to other pathologies after specialist input from a cardiologist.

Respiratory disease

(i) Patients with ILD receiving biologics should be regularly reviewed by a respiratory physician with a specialist interest in ILD, and ideally in a combined rheumatology/respiratory clinic. Pulmonary function tests (PFTs) should be performed as clinically indicated, usually every 4–6 months (grade 2C, SOA 99%).

Most ILDs share a restrictive pattern, with reductions in lung volumes and a reduced diffusing capacity for carbon

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

monoxide (DLCO). Low baseline forced vital capacity (FVC) and DLCO (e.g. FVC <60% and DLCO <40% of predicted values) are independent predictors of early death in patients with IPF. Serial PFTs add information on disease trajectory. Importantly, a short-term (6–12 month) decline in FVC of ⩾10%, or a decline in DLCO of ⩾15%, is associated with increased mortality in IPF [247]. In one systematic review, where ILD occurs subsequent to introduction of anti-TNF, ∼80% of cases were found in the first 20 weeks with a mean of 26 weeks [167].

Although there are no data to suggest the optimal frequency of pulmonary monitoring, we suggest that routine PFT monitoring should be performed as clinically indicated, usually every 4–6 months.

(i) Consideration, in consultation with a respiratory physician with a specialist interest in ILD, should be given to stopping biologic therapy in patients with worsening or new features of ILD. RTX or ABA may be considered in patients with worsening or new ILD (grade 2C, SOA 90%).

Anti-TNF biologics

Patients demonstrating worsening respiratory symptoms or lung function should have the input of a respiratory physician with a specialist interest in ILD to consider the possible causes of the decline as the differential includes causes potentially related to biologic therapy such as infection, congestive heart failure, progression of RA-ILD, drug-induced pneumonitis or other causes not related to biologic therapy such as COPD or pulmonary emboli.

Although it is difficult to establish causation of worsening or new features of ILD to anti-TNF, and in fact an observational study by Herrinton *et al*. [162] found that anti-TNF therapy was not associated with a diagnosis of ILD in RA patients over a mean follow-up of 3 years, we would still recommend consideration of discontinuation of anti-TNF in these circumstances until data from further, larger studies is available.

Non-anti-TNF biologics

Although it is difficult to establish causation of worsening or new features of ILD to any of the non-anti-TNF biologics, a decision to discontinue therapy should be taken in conjunction with respiratory specialist colleagues with the understanding that based on current levels of evidence, ILD is unlikely to be caused or exacerbated by RTX, ABA or TCZ. There are no data available regarding UST in this context.

Uveitis

(i) If patients develop uveitis while on a biologic a trial of an alternative biologic could be considered, bearing in mind the latest reported relative risks (grade 1C, SOA 99%).
(ii) Consider switching patients with uveitis currently taking ETN to INF or ADA (grade 2C, SOA 98%).

Anti-TNF biologics

Refer to the earlier section on uveitis.

Non-anti-TNF biologics

There has been one case report of a patient with RA treated with TCZ who developed acute anterior uveitis 5 weeks after stopping TCZ [248]. Causality is difficult to establish here and indeed TCZ has been used with moderate success in patients with uveitis [173]. There are no data concerning RTX, ABA or UST and the development of uveitis.

Demyelinating disease

(i) Anti-TNF should be withdrawn if demyelination occurs. Rechallenge with anti-TNF therapy is not recommended (grade 2B, SOA 99%).

Any suspected cases of demyelination should be investigated and reported appropriately and referred urgently to a neurologist. The rationale behind this statement is covered in the earlier section on demyelinating disease.

Sixteen cases of Guillain–Barré syndrome were identified from the FDA database following anti-TNF therapy [249]. Among the 13 patients for whom follow-up data were available, one patient experienced no resolution, nine patients had partial resolution and three patients had complete resolution of Guillain–Barré syndrome following therapy.

There are some reports of successful rechallenge with anti-TNF without recurrence of neurological symptoms, but there are also reports of worsening symptoms or recurrence on rechallenge.

Diverticular disease

(i) TCZ should be withdrawn if bowel perforation occurs; reintroduction of TCZ in such patients is not recommended (grade 2C, SOA 99%).

Refer to the earlier section on diverticular disease.

CTD

(i) If a lupus-like syndrome or other significant autoimmune disease develops while on anti-TNF therapy, treatment should be discontinued and appropriate interventions should be initiated. In such instances, a non-anti-TNF biologic should be considered. Rechallenging with an alternative anti-TNF agent should only be undertaken with caution (grade 1C, SOA 99%).

Anti-TNF biologics

There continue to be further case reports of lupus-like syndromes, vasculitis and other autoimmune conditions developing after the commencement of anti-TNF therapy that improve on cessation of the anti-TNF, but often requiring alternative immunosuppression in more severe cases. Full-blown anti-TNF induced lupus or vasculitis remains rare.

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

In a study by Takase *et al*. [250], 18% of patients had ANA seroconversion (83 of 454) when monitoring ANA results while on an anti-TNF, with seroconversion after a median period of 11 months. Only three of these patients were classifiable as lupus, however. BSRBR-RA reported on 11 394 anti-TNF patients followed for a total of 26 927 person-years [251]. Forty anti-TNF-treated patients developed a new lupus event, compared with only one of the DMARD-treated patients (adjusted IRR = 3.17, 95% CI: 0.38, 26.26). The most common lupus symptom was skin rash; LN or neuropsychiatric symptoms were not reported.

Ramos-Casals *et al*. [252] identified 379 patients affected by an autoimmune condition induced by an anti-TNF through a Medline search up to May 2008. SLE/lupus-like disease was found in 105 patients. SLE criteria met were most commonly ANA positive, anti-dsDNA positive, malar rash then arthritis, with <10% having renal or CNS involvement. Treatment was anti-TNF withdrawal in 93% of cases. Thirty-six patients needed steroid or immunosuppression. Mean follow-up was 10 months, and all improved.

A retrospective review of Mayo clinic records 1998–2011 [253] looked at the clinical features, histopathological features and outcomes where diagnosis of vasculitis induced by anti-TNF had been made. Cutaneous small vessel vasculitis was the most common but systemic involvement including peripheral nerve and renal vasculitis was frequently observed; mean duration of anti-TNF prior to development of vasculitis was 34.5 months (2–72 month range). Follow-up after vasculitis was a mean 27.1 months (1–108). No recurrence was seen in these patients on stopping anti-TNF and there was a mean time of 6.9 months to resolution of vasculitis after stopping anti-TNF with all receiving adjuvant treatment. No patients were rechallenged with an anti-TNF agent.

In conclusion there are reports to suggest a small number of patients are at risk of developing a lupus or vasculitis problem when treated with anti-TNF but it is rare to have major organ involvement and symptoms usually resolve on stopping anti-TNF. Although only small numbers of patients have been rechallenged with anti-TNF, when undertaken this led to recurrence in up to 75%, hence the recommendation to use caution if considering rechallenge [252, 254, 255].

Non-anti-TNF biologics

There are no data to suggest an association between any of the non-anti-TNF biologics and induction of autoimmune CTD or vasculitis.

Haematological disorders

(i) Biologic therapies may be continued in patients at increased risk of, or with, venous thromboembolism (VTE) (grade 2C, SOA 99%).

Anti-TNF biologics

Although some studies have reported a potential increased risk of VTE in anti-TNF users [256], a retrospective cohort study using BSRBR-RA data compared the rates of VTE in RA treated with anti-TNF ($n = 11881$) with those treated with csDMARD ($n = 3673$) and found no difference in the rates of VTE between anti-TNF and csDMARDs [257]; the risk was similar across all anti-TNF agents. The study was, however, not powered to detect differences of small magnitude. It should be noted that the observational nature of the BSRBR-RA predisposes to channelling bias (patients with more severe disease are more likely to be enrolled into the anti-TNF cohort). Therefore, continuation of biologic therapies in patients at increased risk can be recommended, as, in addition, higher disease activity may predispose to a prothrombotic state [258]. Risk would also be increased if active disease caused immobility.

Non-anti-TNF biologics

There are no data to suggest that any of the non-anti-TNF biologics increase the risk of VTE.

Psoriasis

(i) If psoriasis develops in patients treated with anti-TNF, conventional psoriasis treatment should be started and consideration should be given to stopping anti-TNF if the skin lesions persist despite specialist dermatology input or are severe (grade 2B, SOA 99%).

Anti-TNF biologics

Several studies have suggested that anti-TNF agents may paradoxically increase an individual's risk of developing psoriasis, despite these agents being licensed and approved by NICE for the treatment of psoriasis.

BSRBR-RA compared 9826 RA patients receiving anti-TNF agents (either IFX, ETN or ABA) against 2880 csDMARD patients [259]. Over 520 person-years of follow-up, 25 cases of new onset psoriasis were observed in those receiving anti-TNF, 52% of which occurred within the first 6 months of therapy, compared with 0 cases in the csDMARD group; this equated to a crude IR of 1.04 (95% CI: 0.67, 1.54) *vs* 0 (95% CI: 0.71) per 1000 person-years. In this cohort, the highest rates of psoriasis were found with ADA compared with ETN and INF.

A higher incidence of psoriasis has also been found in the BIOBADASER cohort [260]. Out of 4437 patients receiving first-generation anti-TNF agents, 32 cases of psoriasis were observed, with an IR of 2.31 (95% CI: 1.69, 3.15). In this cohort, the highest event rate was noted for INF, and the lowest for ETN.

The majority of patients who develop psoriasis while receiving anti-TNF agents do not stop therapy, and are able to manage the condition with add-on therapy [258, 260, 261]. In the BSRBR-RA cohort, only 4 of the 13 patients who developed psoriasis in the first 6 months of anti-TNF therapy stopped treatment due to psoriasis; all reported improvement in psoriasis after stopping therapy [258]. Similarly, a retrospective review of the Mayo clinic experience identified 56 RA patients who developed psoriasis while receiving anti-TNF treatment [260]. Of these, 62% continued with therapy and were treated

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

successfully with add-on medication, although higher rates of complete skin remission were observed in those that stopped treatment. The most common forms of psoriasis that occurred in this cohort were plaque psoriasis and palmopustular psoriasis. A literature review by Collamer and Battafarano [262] found that around 50% of patients who switch to an alternative ant-TNF agent due to psoriasis will not experience a recurrence of their lesions.

Non-anti-TNF biologics

There is no convincing data to suggest an association between any of the non-anti-TNF biologics and the development of psoriasis.

Vaccinations

(i) The Public Health England recommendations on the use of immunizations in patients on immunosuppressive therapy should be adhered to in patients on biologics. Live attenuated vaccines, such as the HZ vaccine, oral polio or rabies vaccine, should be avoided (grade 2C, SOA 99%).

Public Health England recommend that live attenuated vaccines should not be routinely given to individuals who are immunosuppressed (including those receiving biologic therapy). Live attenuated organisms can replicate in an immunosuppressed individual and cause an extensive, serious infection. If the use of live vaccines is necessary, at least 2 weeks, but preferably 4 weeks should be allowed before anti-TNF therapy is commenced.

In terms of travel advice, yellow fever is a live vaccine and must not be given, and therefore patients should be advised not to travel to countries requiring this (e.g. mid-African nations). An exemption statement may be given if a patient has to travel but the patient will be at risk.

Measles, mumps and rubella are live vaccines, so should not be given to a patient on anti-TNF but the vaccine is not contraindicated in household contacts. Exposure to measles should be treated with immunoglobulin regardless of prior immunization [263].

BCG vaccine for TB is contraindicated in patients on anti-TNF treatment as it is also a live vaccine [264].

Polio vaccine is an inactivated vaccine so may be given to immunosuppressed individuals (live polio vaccine was used up until 2004 in the UK) [265].

(ii) Although there may be an attenuated response (particularly if MTX is co-prescribed), patients on biologics should receive influenza and pneumococcal immunizations unless there are contraindications (grade 1C, SOA 99%).

Patients receiving immunosuppressive therapy are advised to have both influenza and pneumococcal immunization. A limited number of studies are available investigating the response to vaccination in rheumatoid patients, with assessments made on RA patients treated with either MTX alone or in combination with anti-TNF.

Influenza immunization

Anti-TNF biologics

There is some evidence that there are differences in response to immunization between each of the first-generation anti-TNF agents. While ADA has been shown not to reduce responsiveness to immunization [266], some studies have suggested that ETN and INF administration is associated with decreased response rates [267, 268]. A study by Elkayam *et al*. [269] showed an adequate response overall to influenza vaccine in patients with RA on INF, but a slightly attenuated response in the group that were vaccinated 3 weeks after receiving INF rather than on the same day. However, numbers were small (38 patients on INF, seven given vaccine 3 weeks after INF) [269]. A review [267] of influenza studies has indicated that this immunization is well tolerated; however, a subset of patients may remain unprotected. Some patients may be concerned that the influenza vaccine may provoke a flare of their RA. However, reassuringly, a recent study published by Milanetti *et al*. [270] noted no increase in flares of RA in patients receiving influenza immunizations, but a slight increase in minor systemic and local side effects such as fever, injection site swelling, headaches and myalgia.

Non-anti-TNF biologics

The efficacy of the influenza vaccine in patients treated with RTX has been examined in several cohort studies. A meta-analysis by Hua *et al*. [271] has shown that some response occurs, but it is attenuated if the patient is on the drug. Response rates may improve if vaccination is given further away from the last RTX infusion; Westra *et al*. [272] found that the IgG response to vaccination was restored in patients who had received RTX 6–10 months prior to vaccination. IgM response, however, did not change.

There is a small amount of evidence regarding the other non-anti-TNF biologics and their effect on response to influenza vaccine. A small Brazilian study of 11 RA patients receiving ABA found a reduced immune response to the influenza vaccine [273]. There are no data concerning TCZ and UST and the influenza vaccination.

Although there are limited data and the suggestion that response to vaccination may be attenuated, because non-anti-TNF biologics are immunosuppressive medications, it is recommended that all patients receiving biologic therapies continue to have a yearly influenza vaccination.

Pneumococcal immunization

Anti-TNF biologics

While MTX is associated with lower response rates to pneumococcal vaccines in most studies [274–277], some studies have suggested that ETN or INF in combination with MTX are not associated with a poor response [266, 274–276]. The reasons for these differences are unclear, but the theory that certain anti-TNF agents can lead to enhanced immune responses was put forward from one study [274], where patients with MTX had lowered responsiveness, but this does not explain why those

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

with the combination of INF or ETN with MTX had even better response rates than the healthy controls.

In the case of ADA, ADA alone has not been shown to affect the antibody titre response to pneumococcal immunization, but the combination of MTX and ADA was shown to be associated with decreased response rates when compared with MTX alone [266].

More recent evidence from a Swedish case–control study [278] in a group of 505 patients with RA or SpA showed adequate response rates to pneumococcal vaccine. Better antibody response ratios were seen in patients on anti-TNF monotherapy, compared with those treated with MTX or MTX plus anti-TNF. Ongoing MTX was predictive of reduced response.

Overall, pneumococcal vaccine is recommended in patients receiving anti-TNF therapy, but clinicians should be aware that the response to vaccination may be attenuated if anti-TNF and MTX are used in combination.

Non-anti-TNF biologics

A small study by Crnkic Kapetanovic *et al*. [279] found that among 88 patients with RA, the antibody response to the pneumococcal vaccine was reduced most notably for RTX, but also with ABA; TCZ, on the other hand, was associated with a sufficient antibody response. There are no data regarding treatment with UST and response to the pneumococcal vaccine.

(iii) In patients who are currently receiving biologics, human papillomavirus vaccine for cervical cancer risk in young women is recommended if they have already received part of the vaccination schedule, as per national guidelines (grade 2C, SOA 99%).

There is a national human papillomavirus (HPV) childhood vaccination programme in place in the UK, introduced in 2008 for secondary-school-age girls of 12–13 years, although girls may receive their HPV vaccination programme up to their 18th birthday. There are no data for the two-dose schedule for immunocompromised patients, and therefore the three-dose schedule should be given if a girl has already started or is due to start anti-TNF therapy. National advice states that re-immunization should be considered after treatment has finished or recovery occurred, and specialist advice may be required [280]. Kumar *et al*. [281] described reduced immunogenicity in organ transplant recipients.

Although most at-risk individuals will have received papillomavirus vaccine in childhood, there may be scenarios where young adults receiving biologics over the age of 18 have not received vaccination. We suggest that in these circumstances, vaccination should be offered, even though the individual is outside of the national vaccination programme age window.

Peri-operative care

(i) The potential benefit of preventing post-operative infections by stopping biologics (different surgical procedures pose different risks of infection and wound healing) should be balanced against the risk of a peri-operative flare in disease activity (grade 2B, SOA 97%).

(ii) For most biologics (exceptions: RTX and TCZ), consideration should be given to planning surgery when at least one dosing interval has elapsed for that specific drug; for higher risk procedures consider stopping 3–5 half-lives (if this is longer than one dosing interval) before surgery (grade 2B, SOA 97%).

(iii) Biologics may be recommenced after surgery when there is good wound healing (typically around 14 days), all sutures and staples are out, and there is no evidence of infection (grade 1B, SOA 99%).

(iv) For patients receiving RTX, treatment should ideally be stopped 3–6 months prior to elective surgery (grade 2B, SOA 94%).

(v) For patients receiving TCZ, i.v. TCZ should be stopped at least 4 weeks before surgery; s.c. TCZ should be stopped at least 2 weeks before surgery (grade 1C, SOA 96%).

Anti-TNF biologics

Current literature provides conflicting data with regard to the risk of infection peri-operatively in association with anti-TNF therapy. A Dutch retrospective study [282] of 1219 surgical procedures in RA patients found that peri-operative continuation of anti-TNF therapy did not seem to be an important risk factor for surgical site infection. This is supported by evidence from several smaller studies [283, 284]. Larger studies from Canada [285], Japan [286] and Germany [287] showed no significant differences in surgical site infection rates in patients on anti-TNF therapy compared with csDMARDS; however, biologic therapy was withheld peri-operatively in >80% of cases. Another Japanese study of orthopaedic surgery found no statistically significant increase in the incidence of delayed wound healing or superficial infection with anti-TNF agents [288]. There was no correlation between peri-operative disease activity, dose of ETN (25 *vs* 50 mg) or preoperative waiting period off biologics (<14 or >14 days) and likelihood of adverse events.

Conversely, other studies have reported an increased risk of peri-operative infection rates with continued use of anti-TNF agents [289]. One report showed that the continuation of anti-TNF therapy was associated with an increased risk of peri-operative infections (OR = 4.4, 95% CI: 1.10, 18.41) in a series of 91 RA patients undergoing orthopaedic procedures [290]. Data from the BSRBR-RA [291] showed that the risk of serious post-operative infection was nearly 2-fold higher in patients who received anti-TNF therapy in the 28 days prior to surgery than in those who were not exposed.

Two further Japanese studies have supported these findings, with suggestion of even greater increased risk of peri-operative infection on anti-TNF. A retrospective cohort study of 420 women with RA, Momohara *et al*. [292] found that anti-TNF agents (INF, ETN, ADA) increased the risk of surgical site infection 9-fold. A

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

Table 7 Dosing intervals, recommendations for timing of surgery and half-lives of biologic therapies

Drug	Dosing interval	Period in which surgery should be scheduled (relative to last biologic dose administered)	One half-life, days	Five half-lives, days
Adalimumab	Every 2 weeks	Week 3	14	70
Abatacept i.v./s.c.	Monthly (i.v.) weekly (s.c.)	Week 5 Week 2	14	70
Certolizumab	Every 2 weeks Every 4 weeks	Week 3 Week 5	14	70
Etanercept	Weekly or twice weekly	Week 2	3	15
Golimumab	Every 4 weeks	Week 5	14	70
Infliximab	Every 4, 6 or 8 weeks	Week 5, 7 or 9	9	45
Rituximab	Two doses 2 weeks apart, no more frequent than every 6 months	Months 4–7	18	90
Tocilizumab i.v.	Every 4 weeks	Week 5		
4mg/kg			11	55
8mg/kg			13	65
Tocilizumab s.c.	Every week	Week 3	13	65
Ustekinumab	Every 12 weeks	Week 13	21	105

higher risk still was identified in a smaller case–control study of 64 patients [293]; INF and ETN were associated with an OR of 21.8 for surgical site infection (95% CI: 1.231, 386.1; $P = 0.036$). ETN was withheld for 2–4 weeks prior to the operation and INF for 4 weeks prior to the surgery. Critics have suggested that the cases of infection were overstated, however, as infections were counted 'when surgeons diagnosed or suspected a surgical infection, and antibiotics were given prophylactically'. Surgeons were not blind regarding which patients had been exposed to anti-TNF therapy, and so could have had a higher index of suspicion for infection in patients on anti-TNF and hence be more likely to prescribe antibiotics [294]. Blinded, prospective studies are therefore needed before firm conclusions can be drawn about the infection risk associated with anti-TNF agents.

In 2008, Pappas and Giles [295] identified six major studies investigating the peri-operative infection risk of anti-TNF therapy associated specifically with orthopaedic surgery. All studies assessed involved retrospective outcome data and the source populations differed greatly between studies making direct comparison difficult. Of the six published major studies, only one study [290] identified an increased risk associated with peri-operative anti-TNF exposure, but the authors recommended that anti-TNF therapy should be stopped for a duration of three to five times their half-lives pre-operatively and restarted once the wound healing is deemed satisfactory (10–14 days). The half-lives of biologic therapies are shown in Table 7. This may be manageable for those biologic agents with reasonably short half-lives, but with agents such as ADA and ABA, where five times the half-life equates to >2 months, cessation for this prolonged period of time is likely to lead to potentially significant (and possibly irreversible) declines in the disease control and major flare, often requiring steroid therapy (and the associated risks, which may be higher than biologic therapy).

Pragmatically we suggest that surgery should be arranged for the week after the next scheduled dose of anti-TNF, and longer still (preferably five half-lives) if the surgery is deemed to be of especially high infection risk by the surgical team. With INF, five half-lives of the drug (45 days) may actually be shorter than the dosing interval, for example, patients receiving INF every 8 weeks. In this situation, ensuring that one dosing interval has elapsed before surgery should be sufficient even with procedures deemed to have a higher risk of infection. The idea behind this dosing principle is that the nadir of the drug's effect would be at the end of its dosing interval. This is in line with advice from a recently published systematic review by the ACR and American Association of Hip and Knee Surgeons [296].

Non-anti-TNF biologics

There is a paucity of data specific to non-anti-TNF biologics and peri-operative care.

A retrospective study using the French AIR registry [297] identified 133 patients who had received RTX prior to a surgical procedure. Eight (6.7%) of the patients experienced a post-operative complication, including eight site infections and one deaths due to septic shock. Post-operative complications were higher in orthopaedic than abdominal surgery; however, only a significant association was seen with spinal surgery ($P = 0.048$). All patients had stopped RTX prior to surgery a mean of 6.4 months beforehand (interquartile range 4.3–8.7 months). There was no difference in event rates according to length of time off therapy prior to surgery. Unfortunately the study could not differentiate between acute and elective procedures, but 68% of procedures were orthopaedic. The number of complications was small and whether the time from infusion to complication of surgery is a major factor was difficult to interpret.

TCZ is a very potent suppressor of acute phase response. A retrospective study looking at 161 patients on

Downloaded from https://academic.oup.com/rheumatology/article/58/2/e3/5076446 by guest on 03 February 2023

TCZ for RA undergoing orthopaedic surgery found 20 patients with wound healing delay, and three post-operative infections, two of which were superficial [292]. This study had no comparator, so conclusions are difficult to draw. Another study comparing patients undergoing surgery on TCZ and csDMARDS found those on TCZ did not mount as high a fever or as significant a rise in CRP as the csDMARD group. Following an infusion of i.v. TCZ, CRP and other markers of acute phase response reach a nadir between 1 and 3 weeks and then gradually return to normal. Although data are lacking, monitoring for post-operative infections in the first 4 weeks following a TCZ infusion is likely to be significantly hampered by a blunted acute phase response. Patients having i.v. or s.c. TCZ might need close monitoring in the post-operative period as the conventional indicators of sepsis (fever and acute phase response) might not be reliable. There are no data regarding ABA and UST in the peri-operative period.

Until further evidence is available, and considering the balance between the potential risk of peri-operative complications *vs* the potential for disease flare if patients are without therapy for a prolonged period of time, we suggest that RTX is stopped at least 3–6 months prior to elective surgery; i.v. TCZ should be stopped at least 4 weeks prior to and s.c. TCZ at least 2 weeks prior to surgery. For all other non-anti-TNF biologics we suggest that surgery should be arranged for the week after the next scheduled dose of anti-TNF, and longer still (preferably five half-lives) if the surgery is deemed to be of especially high infection risk by the surgical team.

Applicability and utility

Clinician responsibility

These guidelines represent a framework upon which clinical practice should be based. However, as with any guideline, individual patient circumstances can have important influences on clinical decision-making, and clinicians should continue to work alongside patients to make shared decisions about care. Failure to adhere to these guidelines should not necessarily be considered negligent, nor should adherence to these recommendations constitute a defence against a claim of negligence.

Potential organizational barriers to the guideline

Biological therapy initiation should only take place under the supervision of an expert in the management of rheumatic disease (i.e. a consultant rheumatologist)—a recommendation supported across the NICE guidelines across the rheumatic disease areas.

An important consideration regarding biologic therapy monitoring is the impact of frequent blood monitoring on health care services. Effective biologic therapy monitoring requires systems in place not only to ensure patients have regular blood tests, but also that the results of tests are reviewed and acted upon appropriately within a timely manner.

The guideline makes three specific recommendations that will increase monitoring burden, as described below.

All patients to be reviewed for drug safety in a specialist rheumatology department at least every 6 months. High risk patients (e.g. those at high risk of TB) should be reviewed every 3 months.

Patients prescribed a biologic (other than TCZ) without concomitant csDMARD or with csDMARDs that do not require blood monitoring should have monitoring blood tests (FBC, renal and liver function) every 3–6 months.

Patients prescribed i.v. or s.c. TCZ, with our without MTX, should have monitoring blood tests (FBC, liver function) every 4 weeks.

Audit tool

A model audit tool template is available for biologic therapy imitation and monitoring. The audit tool can be accessed via the BSR website.

Overall summary and conclusions

Biologic therapies represent a major advance in the treatment of IA, and appropriately their use continues to increase. Information on the longer term safety of these drugs continues to be collected both at a local level and through national registries across the world. Data remain scarce for the second-generation TNF inhibitors (CZB and GOL) and some of the newer non-anti-TNF biologic therapies (such as TCZ, ABA and UST). Similarly, there is a paucity of longer term observational safety data for any of the biosimilar therapies recently licensed and in increasing use worldwide. As questions in many commonly encountered clinical scenarios remain unanswered, it is essential that data on the safety of these products continue to be captured and reported, to inform further updates of this guideline.

Funding: No specific funding was received from any bodies in the public, commercial or not-for-profit sectors to carry out the work described in this manuscript.

Disclosure statement: C.R.H. has been sponsored to attend meetings by AbbVie, Pfizer, Bristol-Myers Squibb and UCB and has received honoraria for speaking and attended advisory boards with AbbVie, Bristol-Myers Squibb, Pfizer, UCB, Janssen and Novartis. R.S. has received sponsorship to attend the national BSR conference from Pfizer and has received honoraria to speak at regional educational meetings by AbbVie and Eli Lilly. M.B. has been sponsored to attend regional, national and international meetings by UCB Celltech, Roche/Chugai, Pfizer, AbbVie, Merck, Mennarini, Janssen, Bristol-Myers Squibb, Novartis and Eli Lilly and received honoraria for speaking and attended advisory boards with Bristol-Myers Squibb, UCB Celltech, Roche/Chugai, Pfizer, AbbVie, Merck, Mennarini, Sanofi aventis, Eli Lilly, Janssen and Novartis. A.M. has received honoraria for sponsored presentations from MSD, Bristol-Myers Squibb and Roche and received an honorarium from Pfizer for professional services. C.H. has received sponsorship to attend a national meeting by Pfizer. E.C. has received sponsorship to attend meetings by Pfizer and UCB and received honoraria for speaking for Eli Lilly.

Guidelines

The British Society for Rheumatology Guideline for the Management of Gout

Michelle Hui[1], Alison Carr[2], Stewart Cameron[3], Graham Davenport[4], Michael Doherty[5], Harry Forrester[4], Wendy Jenkins[5], Kelsey M. Jordan[6], Christian D. Mallen[4], Thomas M. McDonald[7], George Nuki[8], Anthony Pywell[5], Weiya Zhang[5] and Edward Roddy[4,9] for the British Society for Rheumatology Standards, Audit and Guidelines Working Group

Scope and purpose

Background to the disease

Gout is the most common cause of inflammatory arthritis worldwide. In UK general practice, the overall prevalence has increased from 1.4% in 1999 to 2.49% in 2012 [1], despite the availability of effective and potentially curative urate-lowering drugs for >50 years and evidence-based British and European management guidelines for nearly a decade [2, 3].

Clinical manifestations of gout resulting from monosodium urate crystal deposition include tophi, chronic arthritis, urolithiasis and renal disease as well as recurrent acute arthritis, bursitis and cellulitis. Gouty arthritis and tophi are associated with chronic disability, impairment of health-related quality of life [4–7], increased use of healthcare resources and reduced productivity [8]. Gout is also frequently associated with co-morbidities such as obesity, dyslipidaemia, diabetes mellitus, chronic renal insufficiency, hypertension, cardiovascular disease, hypothyroidism, anaemia, psoriasis, chronic pulmonary diseases, depression and OA [1] as well as with an increase in all-cause mortality (adjusted hazard ratio 1.13, 95% CI: 1.08, 1.18) and urogenital malignancy [1, 9].

Sustained hyperuricaemia is the single most important risk factor for the development of gout. Hyperuricaemia occurs secondarily to reduced fractional clearance of uric acid in > 90% of patients with gout [10]. Age, male gender, menopausal status in females, impairment of

NICE has accredited the process used by the BSR to produce its guidance for the management of gout. Accreditation is valid for 5 years from 10 June 2013. More information on accreditation can be viewed at www.nice.org.uk/accreditation. For full details on our accreditation visit: www.nice.org.uk/accreditation.

renal function, hypertension and the co-morbidities that comprise the metabolic syndrome are all risk factors for incident gout associated with decreased excretion of uric acid, as are the use of diuretic and many anti-hypertensive drugs, ciclosporin, low-dose aspirin, alcohol consumption and lead exposure. Tophi and chronic arthritis [11], alcohol consumption [12] and recent use of diuretic drugs [13] are important risk factors for recurring flares.

Genome-wide association studies have identified a number of genes coding for urate anion transporters expressed in the proximal renal tubular epithelium, but these account for <5% of the variation in serum urate [14]. Serum urate levels are influenced by dietary intake and synthesis as well as by renal excretion. Diets high in red meat or seafood, and increased consumption of beer, spirits and fructose- or sugar-sweetened soft drinks are established risk factors for developing gout [15–17]. Single gene disorders associated with urate overproduction, hyperuricaemia and accelerated purine synthesis *de novo* (such as glycogen storage diseases and Lesch–Nyhan syndrome) are very rare causes of primary gout. Diseases (such as lympho- and myeloproliferative disorders and severe exfoliative psoriasis) and drugs (such as cytotoxics, vitamin B12 and ethanol) associated with increased cellular turnover and destruction can lead to secondary hyperuricaemia and gout [18].

The identification of monosodium urate crystals in joint and tissue samples remains the gold standard for the diagnosis of gout. Although identification of urate deposits by dual-energy CT [19] and US [20] are being used increasingly as an aid to the diagnosis of gout in research and hospital practice, joint aspiration or imaging to confirm crystal presence is rarely undertaken in primary care settings where the majority of patients with gout are managed. For diagnosis in clinical practice, clinical scores, without imaging or synovial fluid analysis, have been proposed [21] that include consideration of the patient's history and co-morbidities.

Need for revised management guideline

The British Society for Rheumatology/British Health Professionals in Rheumatology (BSR/BHPR) guideline for the management of gout was published in 2007 [2]. There are four broad reasons why a revised and updated guideline is now required. First, new pharmaceutical treatment options have become available and the evidence base for the efficacy and safety of available drugs has expanded. Second, the incidence, prevalence and severity of gout have increased [1] despite the availability of safe, effective and potentially curative therapy. Third, research studies and audits have consistently shown that fewer than 50% of patients with gout seen in general practice receive urate-lowering therapy (ULT) [22–25] and that many patients with gout being treated with ULT in both primary [1, 26] and secondary care [27, 28] do not achieve reductions of serum uric acid (sUA) levels to the target level recommended in the BSR/BHPR (300 μmol/l) or EULAR (360 μmol/l) guidelines. Finally, as evidence has accumulated that the provision of information to patients with gout is suboptimal [29] and qualitative studies have begun to define a range of patient and provider barriers to effective care [30–32], preliminary data are emerging that demonstrate that these barriers can be overcome, and outcomes improved, with better provision of information and a package of care based on guideline recommendations [33].

Other guidelines available

Recently published guidelines include the 2012 ACR Guidelines for the Management of Gout [34, 35] and the 2013 evidence-based recommendations for the diagnosis and management of gout by a multinational panel of rheumatologists participating in the 3e initiative [36]. Other national and regional guidelines include the US Agency for Healthcare Research and Quality's 2014 guidelines for Diagnosis of Gout and Management of Gout [37, 38], and the Australian and New Zealand [39] and Portuguese [40] recommendations for the diagnosis and management of gout that arose from the 3e initiative [36]. Updated EULAR recommendations for the management of gout were published in 2016.

Objective

This guideline aims to offer revised and updated, concise, patient-focused, evidence-based, expert recommendations for the management of gout in the UK.

Target audience

The guideline has been developed to provide assistance to doctors and allied health professionals who treat and manage patients with gout in primary care and hospital practice. The guideline should also provide a helpful resource for patients and those responsible for commissioning care for patients with gout in the National Health Service (NHS).

Areas that the guideline does not cover

Evidence-based recommendations for the diagnosis and investigation of gout are not included in this guideline. Some recommendations for the diagnosis of gout are addressed in the recent 3e recommendations for the diagnosis and management of gout [36] and EULAR recommendations for the diagnosis of gout [3] are in the process of being updated [41].

Stakeholder involvement

The guideline has been developed by a Multidisciplinary Working Group of rheumatologists (M.H., M.D., K.J., G.N., E.R.), general practitioners (G.D., C.M.), secondary care physicians with specialist experience in general internal medicine, clinical pharmacology (T.M.), and nephrology (S.C.), allied health professionals (A.C., W.J.), lay patients (H.F., A.P.), and an epidemiologist with expertise in evidence-based medicine (W.Z.), on behalf of the BSR/BHPR Standards, Audit and Guidelines Working Group. The draft guideline was presented and discussed in open session by a multidisciplinary audience at the annual scientific meetings of the BSR in 2014 and 2016. The consensus recommendations were developed without any input

Downloaded from https://academic.oup.com/rheumatology/article/56/7/e1/3855179 by guest on 03 February 2023

from, or consultation with, any pharmaceutical company and potential conflicts of interest of all members of the working group have been fully declared. This guideline has been reviewed and endorsed by the Royal College of General Practitioners.

Rigour of development

Scope of the guideline and strategy for guideline development

The scope of the revised guideline and the key clinical management questions that needed to be addressed were agreed by consensus at an initial face-to-face meeting of the guideline working group after detailed review of the published guideline and results of a systematic literature review. Seventeen clinical management questions (Table 1) were subsequently subjected to additional focused systematic literature searches after transposition into 20 questions in Population, Comparator, Outcome, Time format [42].

Systematic literature search

Systematic literature searches were undertaken by M.H. using MEDLINE 1946 to present, EMBASE 1974 to present, PubMed from inception to present, the Cochrane Controlled Trials Register from inception to present and the ISI Web of Science and AMED databases 1985 to present. An initial literature search in March/April 2012 was updated in June 2015 (see Supplementary table S1, available at *Rheumatology online*, for search strategy).

Inclusion criteria

Articles included were systematic reviews, randomized controlled trials (RCTs), uncontrolled trials, observational studies including cohort, case–control and cross-sectional studies, or those where economic evaluation was made.

Exclusion criteria

Editorials, commentaries, conference abstracts and non-evidence-based narrative/personal reviews were excluded. Studies of hyperuricaemia were included only if they related to the management of gout.

Delphi exercise to generate consensus recommendations

Concise consensus recommendations for the management of gout were developed. Members of the guideline working group were asked to generate a comprehensive list of propositions for the management of gout based on available research evidence and their own clinical expertise after reviewing the published recommendations and the results of the systematic literature reviews. Following elimination of closely similar and overlapping recommendations, a preliminary list of 51 proposed recommendations included 13 for the management of acute gout, 15 relating to education, diet and lifestyle modification, and 23 for the management of recurrent, inter-critical and chronic gout. Consensus for 30 revised draft recommendations was reached after three rounds of a Delphi exercise conducted by email in which propositions with >60% of votes were accepted, those with <20% rejected and those attracting between 20 and 60% of votes reconsidered after amalgamations and minor rewording. The draft recommendations were presented for discussion and feedback at the annual scientific meeting of the BSR in 2014. Final consensus on the most appropriate wording for 21 recommendations was agreed at a second face-to-face meeting of the guideline working group after further minor amalgamations and discussion

Table 1 Principal clinical questions considered

1. In patients with acute gout, does the use of ice packs reduce pain?
2. In patients with acute gout, what medication should be used to manage acute attacks?
3. For patients on diuretic therapy presenting with acute gout, should diuretic therapy be discontinued?
4. What are the potential patient and healthcare professional barriers to management of patients with gout?
5. Is patient education effective for patients with gout and, if so, in what format?
6. Is dietary advice effective in the management of patients with gout?
7. In patients with gout and renal failure, should the dose of allopurinol be adjusted?
8. Should patients with gout be screened for co-morbidities?
9. In patients with hyperuricaemia or gout, when should urate-lowering therapy be commenced?
10. In patients with gout, should allopurinol be used as first-line urate-lowering therapy?
11. In patients with gout, should febuxostat be used as an alternative urate-lowering therapy to allopurinol and, if so, in what situations?
12. In patients with gout, should other medications such as benzbromarone, sulfinpyrazone and probenecid be used?
13. In patients initiating urate-lowering therapy, for how long should prophylactic colchicine be continued?
14. In patients initiating urate-lowering therapy, should canakinumab and rilonacept be used to prevent gout attacks?
15. In patients with hyperuricaemia, gout and hypertension, should an angiotensin II blocker rather than an angiotensin-converting enzyme blocker be used?
16. In patients with gout and hyperlipidaemia, should fenofibrate be used as an adjunctive urate-lowering agent?
17. In patients with debilitating chronic tophaceous gout refractory to oral urate- lowering drugs, or in whom these drugs are contraindicated, should pegloticase be used?

Downloaded from https://academic.oup.com/rheumatology/article/56/7/e1/3855179 by guest on 03 February 2023

of the draft recommendations and the feedback from members of the BSR.

Level of evidence

The level of evidence (LoE) in support of each recommendation was determined (1a: meta-analysis of RCTs; 1b: at least one RCT; IIa: at least one well-designed controlled study without randomization; IIb: at least one well-designed quasi-experimental study; III: at least one non-experimental descriptive study, for example, comparative, correlation or case–control study; IV: expert committee reports, opinions and/or experience of respected authorities) [43]. Where a superior LoE was found, for example, a systematic review for a particular intervention, preceding studies regarding that intervention were not further analysed.

Strength of recommendation

The strength of recommendation (SOR) for each treatment recommendation by members of the guideline development group was graded anonymously on a 0–100 mm visual analogue scale by those present at the final face-to-face meeting and by the others via email.

The SOR for each management recommendation was based on the opinions of the guideline working group after considering the research evidence for efficacy, safety and cost-effectiveness of each treatment proposed, and the personal expertise of each member of the group [44]. This included considerations such as the experts' experience and perception of patient tolerance, acceptability and adherence to the treatment in question, as well as their expert knowledge of any logistic issues involved in the administration of the recommended treatment. A simplified algorithm (Fig. 1) illustrates the suggested care pathway.

Recommendations

Recommendations for management of acute attacks

(i) Educate patients to understand that attacks should be treated as soon as an attack occurs and ensure that patients are aware of the importance of continuing any established ULT during an attack. LoE: IV; SOR: 90% (range 81–100%).

Rationale

The SOR for educating patients to understand the importance of treating acute attacks of gout as early as possible is largely based on common sense, patient experience and expert opinion because of the severity of pain experienced by patients with acute gout. Reduction of pain within 24 h following treatment with an NSAID [45] and with colchicine [46] has, however, been demonstrated in two small placebo-controlled RCTs. The recommendation to continue treatment with urate-lowering drugs during acute gout flares is based on a widespread consensus of expert opinion [2, 34, 47], and qualitative studies that suggest that many patients are unaware of the need to do so [30, 31].

(ii) Affected joints should be rested, elevated and exposed in a cool environment. Bed-cages and ice-packs can be effective adjuncts to management. LoE: Ib (ice-packs), IV (other); SOR: 89% (range 54–100%).

Rationale

The recommendation to rest acutely affected joints is based on widespread patient experience and expert opinion. While there is evidence that urate crystal-induced experimental arthritis in dogs is aggravated by movement and ameliorated by rest [48], there have been no RCTs of rest undertaken in patients with gout. The recommendation for using ice is supported by a Cochrane systematic review of a single small RCT (n = 19) in which topical ice was added to prednisolone and colchicine [49]. In this trial, greater pain reduction (−3.3 cm, 95% CI: −5.84 to −0.82 on 10 visual analogue scale) was observed with adjunctive use of ice packs without additional adverse events. Ice packs may be used as safe adjuncts to pharmacological treatment for acute gout, or when drugs are contraindicated because of multiple active co-morbidities.

(iii) An NSAID at maximum dose or colchicine in doses of 500 μg bd-qds is the drug of choice when there are no contraindications. Choice of first-line agent will depend on patient preference, renal function and co-morbidities. Patients on NSAIDs or cyclooxygenase-2 inhibitors (coxibs) should be co-prescribed a gastro-protective agent. LoE: Ia; SOR: 95% (range 80−100%).

Rationale

Khanna *et al.* [50] recently published a systematic review that included 30 papers examining the management of acute gout. Although NSAIDs are used more often than colchicine in general practice [24], evidence that either is consistently more effective is lacking, so that choice should be determined by individual patient's preference as well as by renal function and co-morbidities.

The efficacy of NSAIDs is supported by a single placebo-controlled RCT of tenoxicam 40 mg daily [45]. Most RCTs have been head-to-head comparisons with no single agent having greater efficacy. There is, however, widespread expert consensus that, where there is no contraindication to do so, NSAIDs should be prescribed at high dose when treating patients with acute gout because of the severity of the pain and inflammation [2, 3, 35]. NSAIDs are, however, frequently contraindicated in patients with renal insufficiency, peptic ulceration or a history of previous upper gastrointestinal haemorrhage or perforation. Selective cyclooxygenase-2 inhibitors such as etoricoxib have equal efficacy and better gastrointestinal tolerability than non-selective NSAIDs [51], but there are ongoing uncertainties about their relative cardiovascular and renal toxicity with chronic administration [52].

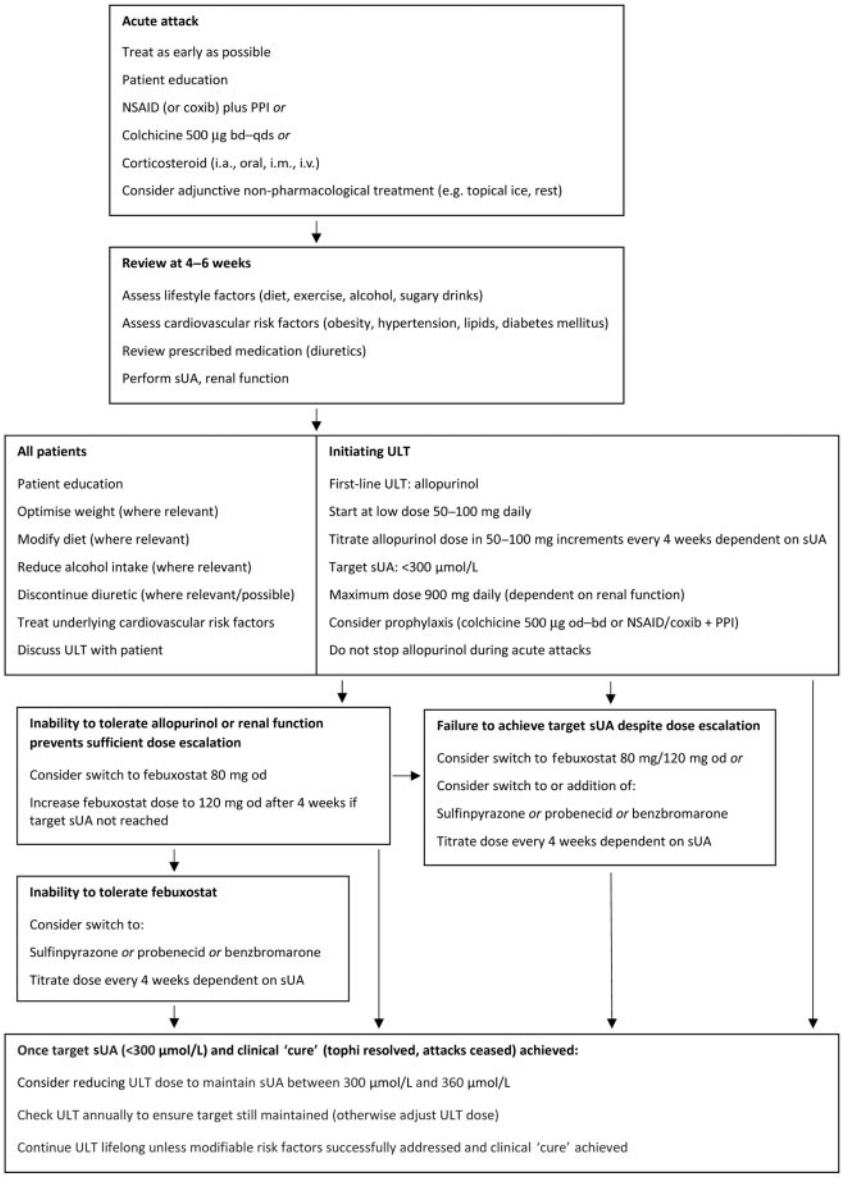
Fig. 1 Algorithm for the management of gout



Acute attack
Treat as early as possible
Patient education
NSAID (or coxib) plus PPI or
Colchicine 500 μg bd–qds or
Corticosteroid (i.a., oral, i.m., i.v.)
Consider adjunctive non-pharmacological treatment (e.g. topical ice, rest)
Review at 4–6 weeks
Assess lifestyle factors (diet, exercise, alcohol, sugary drinks)
Assess cardiovascular risk factors (obesity, hypertension, lipids, diabetes mellitus)
Review prescribed medication (diuretics)
Perform sUA, renal function
All patients
Patient education
Optimise weight (where relevant)
Modify diet (where relevant)
Reduce alcohol intake (where relevant)
Discontinue diuretic (where relevant/possible)
Treat underlying cardiovascular risk factors
Discuss ULT with patient
Initiating ULT
First-line ULT: allopurinol
Start at low dose 50–100 mg daily
Titrate allopurinol dose in 50–100 mg increments every 4 weeks dependent on sUA
Target sUA: <300 μmol/L
Maximum dose 900 mg daily (dependent on renal function)
Consider prophylaxis (colchicine 500 μg od–bd or NSAID/coxib + PPI)
Do not stop allopurinol during acute attacks
Inability to tolerate allopurinol or renal function prevents sufficient dose escalation
Consider switch to febuxostat 80 mg od
Increase febuxostat dose to 120 mg od after 4 weeks if target sUA not reached
Failure to achieve target sUA despite dose escalation
Consider switch to febuxostat 80 mg/120 mg od or
Consider switch to or addition of:
Sulfinpyrazone or probenecid or benzbromarone
Titrate dose every 4 weeks dependent on sUA
Inability to tolerate febuxostat
Consider switch to:
Sulfinpyrazone or probenecid or benzbromarone
Titrate dose every 4 weeks dependent on sUA
Once target sUA (<300 μmol/L) and clinical 'cure' (tophi resolved, attacks ceased) achieved:
Consider reducing ULT dose to maintain sUA between 300 μmol/L and 360 μmol/L
Check ULT annually to ensure target still maintained (otherwise adjust ULT dose)
Continue ULT lifelong unless modifiable risk factors successfully addressed and clinical 'cure' achieved

coxib: cyclooxygenase-2 inhibitor; PPI: proton pump inhibitor; sUA: serum uric acid; ULT: urate-lowering therapy.

Co-prescription of gastro-protection is recommended for patients treated with NSAIDs in accordance with National Institute for Health and Care Excellence (NICE) clinical guidelines [53].

For colchicine, Khanna *et al*. [46, 54] found two placebo-controlled RCTs demonstrating statistical reduction in pain at 24 and 48 h. Terkeltaub's study demonstrated that a low-dose colchicine regimen (1.2 mg followed by 600 μg after 1 h) was equally effective, and was associated with much less nausea, vomiting and diarrhoea, as a high-dose regimen of 4.8 mg over 6 h. A Cochrane review of the same two RCTs [55] also concluded that there was low quality evidence for the efficacy of low-dose colchicine and for no additional efficacy with high doses, which were significantly more likely to be associated with adverse effects (risk ratio (RR) = 3.00, 95% CI: 1.98, 4.54). In the absence of further trial evidence for the efficacy and safety of this proposed regimen, the BSR working group recommends treating acute gout with colchicine in doses of 500 μg bd–qds when there are no contraindications to doing so. The maximum dose of 500 μg qds is, however, often limited by gastrointestinal side effects, most frequently diarrhoea. Colchicine is contraindicated in patients with estimated glomerular filtration rate (eGFR) <10 ml/min/1.73 m^2 and doses should be reduced in patients with eGFR 10–50 ml/min/1.73 m^2 and in the elderly

Downloaded from https://academic.oup.com/rheumatology/article/56/7/e1/3855179 by guest on 03 February 2023

[56]. Colchicine should also only be used with caution and at low doses in patients taking drugs that are potent inhibitors of cytochrome P450 3A4 (e.g. cimetidine, clarithromycin, erythromycin, fluoxetine, ketoconazole, protease inhibitors, tolbutamide) or p-glycoprotein (e.g. clarithromycin, ciclosporin, erythromycin) [57]. Caution is also required when using colchicine in patients receiving statins, particularly in those with renal impairment, as there are case reports of myopathy and rhabdomyolysis following combined use of colchicine and statins [58–60].

(iv) Joint aspiration and injection of a corticosteroid are highly effective in acute monoarticular gout and may be the treatment of choice in patients with acute illness and co-morbidity. A short course of oral corticosteroid or a single injection of an intramuscular corticosteroid is an alternative in patients who are unable to tolerate NSAIDs or colchicine and in whom intra-articular injection is not feasible. Such systemic therapy is also appropriate for oligo- or polyarticular attacks of gout. LoE: Ib (oral), III (intraarticular, intramuscular), IV (oligo/polyarticular attacks); SOE: 94% (range 83–100%).

Rationale

A Cochrane review in 2013 [61] found no RCTs of intra-articular steroid use for the management of acute gout. However, small observational studies, expert opinion and clinical experience suggest that intra-articular and intramuscular steroid injections can be very effective treatments for acute gouty arthritis [62–64].

A Cochrane review of systemic corticosteroids [65] for acute gout included one randomized double-blind equivalence trial that showed that 5-day courses of naproxen 500 mg twice daily and prednisolone 35 mg daily had equal efficacy [66].

(v) In patients with acute gout where response to monotherapy is insufficient, combinations of treatment can be used. LoE: IV; SOR: 80% (28–100%).

Rationale

This recommendation is supported only by expert opinion [67]. A survey in 2006 [68] found that the most commonly used combination agents are NSAIDs with either intra-articular corticosteroids, or oral steroids or colchicine.

(vi) IL-1 inhibitors may be considered in patients who have previously not responded adequately to standard treatment of acute gout (although not approved by NICE). LoE: Ib (canakinumab, rilonacept), III (anakinra); SOR: 61% (range 8–100%).

Rationale

Anakinra, canakinumab and rilonacept are three IL-1 inhibitors that have been investigated to some extent for the management of acute gout [69–74]. In an RCT, the mAb anti-human IL-1β antibody canakinumab (150 mg by subcutaneous injection) showed good efficacy in reducing pain and swelling when compared with 40 mg intramuscular triamcinolone acetonide [69, 70]. Canakinumab is licensed for use in Europe by the European Medicines Agency (EMA) but not in the USA by the Food and Drug Administration (FDA) because of uncertainty about its risk/benefit ratio. There are currently no published RCTs for the use of anakinra, an IL-1 receptor antagonist, in patients with gout. However, an open label study using 100 mg s.c. on three consecutive days demonstrated pain relief in patients with gout who could not tolerate or had failed conventional treatment [72] and a retrospective review of its use off-label in 26 patients suggested that it could be an effective and safe alternative treatment for acute gouty arthritis in medically complex hospitalized patients who fail or cannot undergo more conventional therapy [73].

These findings and ongoing uncertainty concerning the efficacy and safety of IL-1 inhibitors are reflected in a recent Cochrane review [74]. None of anakinra, canakinumab and rilonacept is approved by NICE for use in the treatment of acute gout. Prescribers in the UK should be aware of the potential need to obtain approval for an individual funding request before these drugs are used.

Recommendations for modification of lifestyle and risk factors

(i) If diuretic drugs are being used to treat hypertension rather than heart failure, an alternative antihypertensive agent can be considered as long as blood pressure is controlled. LoE: IV; SOR: 91% (range 85–100%).

Rationale

Thiazide and loop diuretics are used for a number of indications including the management of hypertension, heart failure and other causes of fluid overload. Whilst diuretics have been found to be associated with an increased risk of gout with a rate ratio of 11.8 (95% CI: 5.2, 27.0) [75], blood pressure control may require a number of agents and often includes a diuretic [76]. A systematic review published in 2012 [77] attempted to assess the risk, but as the number of studies was small, it concluded that there was insufficient evidence to recommend the discontinuation of diuretics across all indications in patients with gout. A recent population-based case–control study using the General Practice Research Database demonstrated that while the use of thiazide and loop diuretics was associated with the development of incident gout, the use of potassium-sparing diuretics was not [78].

(ii) All patients with gout should be given verbal and written information about the following: the causes and consequences of gout and hyperuricaemia; how to manage acute attacks; lifestyle advice about diet, alcohol consumption and obesity; and the rationale, aims and use of ULT to target urate levels. Management should be individualized and take into account co-morbidities and concurrent medications. Illness perceptions and potential

Downloaded from https://academic.oup.com/rheumatology/article/56/7/e1/3855179 by guest on 03 February 2023

barriers to care should be discussed. LoE: IIb; SOR: 96% (range 83–100%).

Rationale

There is growing evidence regarding the importance of education in gout. An observational, proof of concept study [33] has demonstrated how education and individualized lifestyle advice along with ULT can achieve therapeutic targets. In this study of 106 participants, 92% achieved the therapeutic target, adherence at 1 year was excellent, and there were improvements in pain and other patient-centred outcomes.

Qualitative studies [30] suggest that an inadequate understanding of the causes and consequences of gout, belief that it is only a man's disease, and a stereotypical view of gout as being entirely self-inflicted through lifestyle abuse are important barriers to care. This may result in gout sufferers being hesitant in seeking medical advice and adhering to pharmacological treatments that are not well explained. Other studies have shown that such negative views about gout and its treatment are associated with lower adherence to ULT and suboptimal control of disease [32, 79, 80]. Patients who do not, or cannot, adhere to prescribed ULT are more likely to experience more gout attacks more frequently and in more joints. Such factors, as well as co-morbid disease, have been found to be associated with poorer health-related quality of life [6]. While patients are frequently interested in details of the influence of dietary constituents, they commonly also have important concerns relating to drug safety and drug interactions that are seldom adequately discussed [31].

(iii) In overweight patients, dietary modification to achieve a gradual reduction in body weight and subsequent maintenance should be encouraged. Diet and exercise should be discussed with all patients with gout, and a well-balanced diet low in fat and added sugars, and high in vegetables and fibre should be encouraged: sugar-sweetened soft drinks containing fructose should be avoided; excessive intake of alcoholic drinks and high-purine foods should be avoided; inclusion of skimmed milk and/or low fat yoghurt, soy beans and vegetable sources of protein, and cherries in the diet should be encouraged. LoE: I (vitamin C and skimmed milk), III (others); SOR: 92% (range 80–100%).

Rationale

A recent systematic review of predominantly observational studies [81] identified a number of modifiable dietary factors that were associated with gout. Excessive consumption of meat, seafood, alcoholic drinks (especially beer and spirits), sugar-sweetened soft drinks and fructose-containing foods are all significant risk factors for incident gout. Episodic excessive alcohol consumption, regardless of type of alcohol-containing beverage, is also associated with an increased risk of recurrent gout attacks [82]. Low-fat dairy intake, folate intake, coffee consumption and diets high in dietary fibre appear to be associated with a reduced risk of incident gout as well as a reduction in risk of recurrent gout flares in some, but not all, cases [83]. Fruit consumption has been found beneficial and this may be related to consumption of vitamin C (see recommendation VIII for the optimal use of urate-lowering therapies).

The urate-lowering effect of cherry was previously reported in healthy women [84]. A case-crossover study conducted in 633 subjects with gout [85] found that consumption of cherry and cherry extract was associated with a statistically significant 35% lower risk of gout attacks when compared with no cherry intake. When cherry intake was combined with allopurinol use, the risk of gout attacks was 75% lower than during periods without either exposure (odds ratio (OR) = 0.25, 95% CI: 0.15, 0.42).

A Cochrane systematic review of the efficacy and safety of dietary supplements in patients with gout found only two RCTs, one for skimmed milk powder (SMP) enriched with glycomacropeptides (n = 120) and the other for vitamin C (n = 40) [86]. Pain from self-reported flares was marginally less in those receiving enriched, compared with unenriched, SMP (mean difference −1.03, 95% CI: −1.96 to −0.10), but enriched SMP was no better in reducing the mean number of acute attacks or the sUA. Vitamin C (500 mg/day for 8 weeks) reduced the sUA (−0.014 mmol/l) much less than allopurinol (−0.118 mmol/l) in patients with gout, and also less than the mean reduction of 0.02 mmol/l reported in the meta-analysis of 13 RCTs of vitamin C administration in patients with hyperuricaemia who did not have gout [87]. Vitamin C supplementation in this modest dose does not appear to have a clinically significant uricosuric effect in patients with gout [87]. It is certainly insufficient for use as monotherapy and a trial suggested that its efficacy as a urate-lowering agent, even when used as an adjunct to standard ULT with allopurinol, was minimal [88].

(iv) Patients with gout and a history of urolithiasis should be encouraged to drink >2 l of water daily and avoid dehydration. Alkalinization of the urine with potassium citrate (60 mEq/day) should be considered in recurrent stone formers. LoE: IV; SOR: 57% (range 17–100%).

Rationale

While there are no published trials of prevention of urolithiasis in patients with gout and recurrent stone formation, there have been two recent systematic reviews and meta-analyses of RCTs of medical management of recurrent urolithiasis in all adults [89, 90]. There is moderate strength evidence from relatively poor quality RCTs for risk reduction with increased fluid intake (RR = 0.45, 95% CI: 0.24, 0.84) and further reduction of risk with additional therapy with citrates (RR = 0.25, 95% CI: 0.14, 0.44).

Downloaded from https://academic.oup.com/rheumatology/article/56/7/e1/3855179 by guest on 03 February 2023

(v) Cardiovascular risk factors and co-morbid conditions such as cigarette smoking, hypertension, diabetes mellitus, dyslipidaemia, obesity and renal disease should be screened for in all patients with gout, reviewed at least annually and managed appropriately. LoE: III; SOR: 90% (range 77–100%).

Rationale

Co-morbidities associated with gout are well recognized [81, 91, 92]. The need to manage these co-morbidities is also recognized but at present no prescriptive guidance exists. An RCT found that allopurinol slows the progression of renal disease in patients with chronic kidney disease (CKD) and hyperuricaemia [93]. The importance of screening for co-morbidities is highlighted by a recent population-based study that has demonstrated gout to be an independent risk factor for mortality from coronary heart disease and renal disease [94].

Recommendations for optimal use of urate-lowering therapies

(i) The option of ULT should be explained to patients when the diagnosis is confirmed and they are being given information about gout. Patients should be fully involved in the decision as to when to commence ULT. The importance of taking ULT regularly and continually to prevent the return of gout attacks should be explained. Patients should be supported during the process of lowering their serum uric acid levels as it can cause an increase in gout flares during this time. LoE: Ib; SOR: 94% (range 82–100%).

Rationale

Reasons for full patient involvement have been discussed earlier in this guideline and are supported by preliminary evidence from a proof of concept study [33]. Poor patient understanding of the need for ULT is not confined to the UK and has been documented in a large population-based observational study in the USA [80], in a survey conducted in South China [95] and in a focus group qualitative study in New Zealand Maoris [96].

(ii) Urate-lowering therapy should be discussed and offered to all patients who have a diagnosis of gout. ULT should particularly be advised in patients with the following: recurring attacks ($\geqslant 2$ attacks in 12 months); tophi; chronic gouty arthritis; joint damage; renal impairment (eGFR < 60 ml/min); a history of urolithiasis; diuretic therapy use; primary gout starting at a young age. LoE: Ia (attacks, tophi, chronic gouty arthritis, joint damage, renal impairment), III (urolithiasis), IV (diuretics, young age). SOR: 95% (range 82–100%).

Rationale

Research evidence supporting the treatment gout with ULT has increased considerably in the last decade. Treatment of patients with recurring attacks, tophi and chronic gouty arthritis is supported by three systematic reviews and meta-analyses [97–99]. However, the recommendation to consider treatment with ULT in all patients with gout is only based on expert opinion and increasing imaging evidence that gout is a chronic crystal deposition disease even at the time of the first attack [100]. For patients known to have other pre-existing risk factors or co-morbidities when presenting with the first episode of gout, such consideration is particularly pertinent. The length of time between the first and subsequent episode of gout can vary considerably between individuals, but typically is < 2 years. Over time, the inter-critical periods shorten and as good practice in patient education, it is worth having the discussion about treatment early in the course of the disease, always bearing in mind that this potentially curable condition can have a significant impact on patient quality of life if left untreated [5, 6]. It is not recommended that asymptomatic hyperuricaemia is treated. However, the wisdom of the recommendation that commencement of ULT should at least be considered after the first attack of gout is supported by observational data from the UK Clinical Practice Research Datalink that showed that less than half the patients with gout eligible for ULT were offered treatment [23].

Earlier recommendations to offer treatment with ULT only to gout patients with recurring acute attacks were supported by a health economic study in a Canadian healthcare setting that showed that only 62% of patients with gout had a second attack within 1 year and that treatment with ULT only became cost-effective (cost saving) in patients suffering more than three attacks per year [101]. This study, however, does not take into account the ongoing silent deposition of crystals and the significant pain experienced by patients with each attack. Clinical experience and epidemiological studies [102, 103] also show that the risk of gout attacks rises sharply when the serum urate is very high (>500 μmol/l). However, the decision as to when to start ULT in any individual will also be influenced by the patient's co-morbidities, any potential contraindications, intolerance or drug interactions, as well as by consideration of the overall balance of risks and benefits and the patient's wishes.

A large population-based study has demonstrated that gout is an independent risk factor for mortality and specifically for death due to coronary heart disease and renal disease [94]. Gout is a risk factor for the development of end-stage renal failure [104] and hyperuricaemia is an independent risk factor for renal impairment [105]. There is now evidence from RCTs that allopurinol slows progression in hyperuricaemic patients with CKD [93, 106] and a recently published systematic review supports the concept that treating gout with ULT improves renal function [55].

Treatment of patients with gout and urolithiasis with ULT is supported by observational studies [107], while the recommendation to consider ULT in patients taking diuretic drugs is supported by three cohort studies and four case–control studies that demonstrated higher risks

Downloaded from https://academic.oup.com/rheumatology/article/56/7/e1/3855179 by guest on 03 February 2023

of gouty arthritis in users compared with non-users of diuretics [77].

The recommendation to treat patients with primary gout at an early age with ULT is largely based on expert opinion. A number of rare monogenic disorders associated with inborn errors of purine metabolism [108, 109], glycogen storage diseases [110] or uromodulin mutations associated with decreased fractional urate excretion [111] can result in the development of gout at an early age. A retrospective study of patients seen by rheumatologists in Taiwan suggested that the age at which gout presents was falling [112] and heritability accounts for 35% of gout risk in men and 17% in women in Taiwan [1]. Common dysfunctional variants in the ABC G2 urate transporter may be important causes of early onset gout in Japanese males [113] and in Han Chinese [114] but ~~e~~vidence from twin studies in the USA suggests that while genetic factors have an important influence on serum urate levels and hyperuricaemia, lifestyle and environmental factors are more important risk factors for primary gout, outside the context of the rare single gene disorders [115].

(iii) Commencement of ULT is best delayed until inflammation has settled as ULT is better discussed when the patient is not in pain. LoE: IV; SOR: 94% (range 87–100%).

Rationale

Although a small RCT has shown that commencement of allopurinol during an acute attack was not associated with a significant increase in daily pain, recurrent flares or inflammatory markers [116], the working group thought that postponing detailed discussion of long term ULT until a time when the patient was no longer in pain would allow the information to be better absorbed. However, in patients in whom attacks are so frequent to make this difficult, the findings of this trial support initiation of ULT before inflammation has resolved.

(iv) The initial aim of ULT is to reduce and maintain the sUA at or below a target level of 300 μmol/l to prevent further urate crystal formation and to dissolve away existing crystals. The lower the sUA the greater the velocity of crystal elimination. After some years of successful treatment, when tophi have resolved and the patient remains free of symptoms, the dose of ULT can be adjusted to maintain the sUA at or below a less stringent target of 360 μmol/l to avoid further crystal deposition and the possibility of adverse effects that may be associated with a very low sUA. LoE: III (sUA target <300 μmol/l), IV (subsequent dose adjustment to sUA <360 μmol/l); SOR: 97% (range 90–100%).

Rationale

The target sUA of <300 μmol/l recommended in the previous BSR/BHPR guideline [2] remains the recommended target to prevent crystal formation and recurrent flares [117]. Evidence that greater velocity of crystal elimination is associated with a lower sUA is derived from observational data [118, 119]. The recommendation for ULT dose reduction to the less stringent target of sUA below 360 μmol/l once the patient is stable to avoid further crystal deposition and the possibility of adverse effects that may be associated with a very low sUA is based on expert opinion, a reasoned proposal for such a two-stage approach [119] and caution in the light of studies that have shown a possible association between low sUA levels and progression of neurodegenerative disorders such as Parkinson's disease [120], dementia [121], Huntingdon's disease [122] and amyotrophic lateral sclerosis [123]. One study showed an increased risk of incident Parkinson's disease in men with sUA <300 μmol/l compared with those with sUA 300–500 μmol/l [124].

(v) Allopurinol is the recommended first-line ULT to consider. It should be started at a low dose (50–100 mg daily) and the dose then increased in 100 mg increments approximately every 4 weeks until the sUA target has been achieved (maximum dose 900 mg). In patients with renal impairment, smaller increments (50 mg) should be used and the maximum dose will be lower, but target urate levels should be the same. LoE: Ib (dose escalation), III (dose adjustment for renal function). SOR: 97% (range 88–100%).

Rationale

Research evidence for the efficacy and safety of allopurinol has been studied in a recent systematic review [125]. Eleven trials involving a total of 4531 patients compared allopurinol in various doses with placebo (two trials); febuxostat (four trials); benzbromarone (two trials); colchicine (one trial); probenecid (one trial); continuous *vs* intermittent allopurinol (one trial); and different doses of allopurinol (one trial). In double blind RCTs, allopurinol given in a fixed dose of 300 mg daily was more effective than placebo [126] but less effective than febuxostat 80 mg or 120 mg daily [126, 127]. However, these trials, and observational studies of gout being treated in UK general practice [33], have shown that many patients do not achieve reductions of sUA to target levels recommended by the BSR (300 μmol/l) [2] or EULAR (360 μmol/l) [3] when treated with allopurinol in doses of 300 mg or less daily. Recent data from the Nottingham proof of concept study [33] and from the Febuxostat versus Allopurinol Streamlined Trial (FAST) [128] have confirmed that gradual up-titration of allopurinol is effective in lowering sUA to target levels and generally well tolerated. The median dose of allopurinol found to be required to achieve the less stringent therapeutic sUA target of ⩽360 μmol/l in >90% of the Nottingham patients was 400 mg/day. While we await direct comparison between allopurinol and febuxostat (and other ULTs) using recommended, best practice, up-titration regimens rather than fixed doses, allopurinol should remain the first option. The recommendation that allopurinol should be the first-line ULT

Downloaded from https://academic.oup.com/rheumatology/article/56/7/e1/3855179 by guest on 03 February 2023

to consider is further supported by health economic studies [129, 130].

Although well tolerated by the majority of patients, allopurinol is rarely (~0.1–0.4%) associated with potentially life-threatening severe, cutaneous adverse reactions (SCAR) including toxic epidermal necrolysis, hypersensitivity drug reactions with rash, eosinophilia and systemic symptoms (DRESS) or Stevens–Johnson syndrome with vasculitis, liver and renal toxicity [131]. Allopurinol should not be used in people carrying the variant allele HLA-B*5801 [132] as the risk of SCAR during treatment with allopurinol is greatly increased (OR = 73) [133]. Screening patients of Korean, Han Chinese and Thai descent for HLA-B*5801 before considering ULT with allopurinol has been recommended [35] because of the high frequency (6–12%) of this allele in these ethnic groups compared with <2% in Caucasian populations.

Based on reports of a relationship between the use of full dose allopurinol and the development of allopurinol hypersensitivity in patients with renal impairment, previous recommendations were to dose allopurinol according to creatinine clearance (CrCl) [134]. Unfortunately subsequent observational studies showed that dose adjustment according to CrCl seldom resulted in adequate reduction of sUA in patients with gout and renal insufficiency [135], and a case–control study showed no evidence of a reduction in frequency of allopurinol hypersensitivity in patients dosed according to CrCl [136]. More recently, studies by Stamp *et al.* [137] have suggested that lowering the starting dose of allopurinol appropriate to the level of renal function (Table 2) reduces the risk of allopurinol hypersensitivity, and that subsequent gradual increase in the dose above the dose based on CrCl resulted in reduction of sUA to target levels in most patients without any increase in toxicity [138].

(vi) Febuxostat can be used as an alternative second-line xanthine oxidase inhibitor for patients in whom allopurinol is not tolerated or whose renal impairment prevents allopurinol dose escalation sufficient to achieve the therapeutic target. Start with a dose of 80 mg daily and, if necessary, increase after 4 weeks to 120 mg daily, to achieve therapeutic target. LoE: Ia; SOR: 90% (range 63–100%).

Table 2 Starting regime of allopurinol according to glomerular filtration rate

Estimated GFR ml/min/1.73 m^2	Allopurinol starting dose
<5	50 mg/week
5–15	50 mg twice weekly
16–30	50 mg every 2 days
31–45	50 mg/day
46–60	50 mg and 100 mg on alternate days

Rationale

Systematic reviews and meta-analyses [97, 99] of RCTs [126, 127, 139], among other RCTs, have demonstrated the efficacy of febuxostat in reducing sUA levels, and reducing the risk of gout flares. When compared with a fixed dose of 300 mg of allopurinol, febuxostat (80 mg and 120 mg/day) was more effective in reducing the sUA to <360 mmol/l (RR = 1.56; 95% CI: 1.22, 2.00) but not the risk of gout flares (RR = 1.16; 95% CI: 1.03, 1.30) [97]. There was heterogeneity in the dosages of febuxostat and allopurinol used, the length of time patients had had gout, the length of follow-up, and whether prophylaxis was used.

Febuxostat is generally well tolerated and can be used in doses of 80 mg or 120 mg daily in elderly patients [140] and others with mild to moderate renal impairment (GFR >30 ml/min/1.73 m^2). There are currently insufficient data available on its use in patients with more severe CKD. Severe cutaneous hypersensitivity reactions to febuxostat [141–144] are very unusual but the risk of SCAR or DRESS with febuxostat in patients with previous allopurinol hypersensitivity has still to be established. Treatment with febuxostat in patients with ischaemic heart disease or congestive cardiac failure is currently not recommended [143, 144] but large scale RCTs are currently in progress in Europe [128] and North America [145] to establish and compare the cardiovascular safety of febuxostat and allopurinol in patients with gout, high cardiovascular risk and co-morbidities.

Health economic studies have shown that febuxostat is cost-effective as a second-line ULT [129, 130]. In the UK, NICE have recommended the use of febuxostat only when allopurinol is contraindicated or not tolerated [144] while the Scottish Medicines Consortium (SMC) accepts febuxostat as a suitable second-line ULT when treatment with allopurinol is inadequate, not tolerated, or contraindicated [146].

(vii) Uricosuric agents can be used in patients who are resistant to, or intolerant of, xanthine oxidase inhibitors. The preferred drugs are sulfinpyrazone (200–800 mg/day) or probenecid (500–2000 mg/day) in patients with normal or mildly impaired renal function, or benzbromarone (50–200 mg/day) in patients with mild to moderate renal insufficiency. LoE: Ia; SOR: 92% (range 82–100%).

Rationale

Uricosuric drugs were the first agents to be used for ULT >60 years ago [147]. Their efficacy and safety for ULT is supported by a recent systematic review and meta-

Downloaded from https://academic.oup.com/rheumatology/article/56/7/e1/3855179 by guest on 03 February 2023

analysis [148] of two RCTs comparing benzbromarone with allopurinol, two RCTs comparing benzbromarone with probenecid and one non-randomized case–control trial comparing probenecid with allopurinol, and a cohort study examining probenecid [149], but there have been no placebo-controlled RCTs of the three drugs that are currently approved for use as ULT in patients with gout in Europe (sulfinpyrazone 200–800 mg od, probenecid 250–500 mg qds, benzbromarone 50–200 mg od). In an RCT of patients who did not tolerate allopurinol 300 mg/day well or achieve target sUA, benzbromarone 200 mg/day was found to be more effective and better tolerated than probenecid 2 g/day [150], and benzbromarone 200 mg daily was approximately equipotent with allopurinol 600 mg/day in lowering sUA to target in another RCT [151]. All uricosurics are contraindicated or need to be used with great caution in patients with urolithiasis or severe renal impairment. Clinical experience indicates that sulfinpyrazone and probenecid have limited efficacy in patients with mild or moderate renal insufficiency (GFR $<$ 60 ml/min) but benzbromarone has been shown to maintain uricosuric efficacy when the GFR is as low as 20 ml/min [152]. Probenecid and benzbromarone are only available for the treatment of patients with gout in the UK on a named patient basis, and patients requiring these unlicensed drugs should be under the care of a rheumatologist. The use of benzbromarone was restricted in Europe following rare reports of severe hepatotoxicity, mainly from Asian countries. Patients treated with benzbromarone should have liver function tests monitored but the risk of serious hepatotoxicity in patients receiving the benzbromarone in Europe is estimated as approximately 1 in 17 000 [153].

(viii) Losartan and fenofibrate should not be used as a primary ULT but where treatment for hypertension or dyslipidaemia, respectively, is required, they may be considered as they have a weak uricosuric effect. Vitamin C supplements (500–1500 mg daily) also have a weak uricosuric effect. LoE: III; SOR: 89% (range 63–100%).

Rationale

Unlike ACE inhibitors, beta blockers and other angiotensin II receptor blockers used for treating hypertension, losartan 50 mg od has been shown to have mild uricosuric effects in patients with gout [154], and the use of losartan was associated with a significantly reduced risk of incident gout (RR = 0.81, 95% CI: 0.70, 0.94) in a large community-based UK case–control study using data from The Health Improvement Network [155].

The lipid-lowering agent fenofibrate has been shown to be uricosuric [156] and to have a modest additional urate-lowering effect in gout patients being treated with allopurinol [157, 158]. Losartan (50 mg od) and fenofibrate (300 mg od) were both found to have some additional urate-lowering efficacy when administered to gout patients receiving ULT with allopurinol or benzbromarone in one small study [159].

A meta-analysis of 13 RCTs found that sUA can be lowered by vitamin C supplementation in patients without gout and that sUA reductions were greater in trials administering vitamin C $>$500 mg/day [87]. A single RCT in patients with gout showed that vitamin C (500 mg/day for 8 weeks) reduced the sUA ($-$0.014 mmol/l) much less than allopurinol ($-$0.118 mmol/l) [88]. Vitamin C supplements in this modest dose only have a very weak uricosuric effect in people with gout, which is insufficient for it to be used as substitute monotherapy for allopurinol or other licensed ULT. Moreover, the study of Stamp suggests that in this dosage it is also unlikely to be a clinically useful adjunct to standard ULT with allopurinol [88]. No studies have been undertaken to assess whether vitamin C supplementation is effective in reducing the incidence of recurrent gout attacks.

(ix) A uricosuric agent can be used in combination with a xanthine oxidase inhibitor in patients who do not achieve a therapeutic serum urate target with optimal doses of monotherapy. LoE: III; SOR: 88% (range 71$-$100%).

Rationale

Enhancement of uric acid excretion and reduction of sUA in patients with tophaceous gout by combined treatment with sulfinpyrazone and allopurinol was first demonstrated nearly 50 years ago [160]. Observational studies by Perez-Ruiz and colleagues have shown that the velocity of tophus volume reduction in patients with chronic tophaceous gout could be accelerated with more profound reduction of sUA by combined treatment with allopurinol and benzbromarone [118]. They subsequently demonstrated that even gout patients that are primary overproducers of urate, with apparently increased urine uric acid excretion, also have evidence of defective fractional urate clearance [161] and may therefore respond to addition of a uricosuric drug if their sUA is not reduced to target levels with a xanthine oxidase inhibitor alone. More recent observational studies have also shown that combined treatment with allopurinol and benzbromarone was more effective in lowering sUA than either agent alone [162]. A recent single case report has demonstrated effective lowering of sUA in a patient with gout and chronic renal failure with addition of a combination of allopurinol and febuxostat to benzbromarone when combination of a single xanthine oxidase inhibitor with benzbromarone was ineffective [163]. Most recently phase III trials of a new selective uric acid reabsorption inhibitor, lesinurad, have shown it to be effective in doses of 200 mg od and 400 mg od in lowering the sUA to target levels in combination with allopurinol in patients with gout that have not responded adequately to allopurinol $\geqslant$300 mg daily ($\geqslant$200 mg in moderate renal impairment) [164]. Its use for this indication has recently been given FDA and EMA approval and marketing authorization.

(x) Colchicine 500 μg bd or od should be considered as prophylaxis against acute attacks resulting from initiation or up-titration of any ULT and continued

Downloaded from https://academic.oup.com/rheumatology/article/56/7/e1/3855179 by guest on 03 February 2023

for up to 6 months. In patients who cannot tolerate colchicine, a low-dose NSAID or coxib, with gastroprotection, can be used as an alternative providing there are no contraindications. LoE: Ib; SOR: 86% (range 29–100%).

Rationale

Prophylaxis against acute flares in patients initiating ULT has been the subject of two recent systematic reviews [125, 165]. There is more evidence from RCTs to support the use of colchicine, than for NSAIDs, for flare prophylaxis. In a 6-month placebo-controlled RCT in patients with gout receiving probenecid for ULT, the flare rate was reduced from 6 to 2.3 flares per annum in patients receiving colchicine 500 μg daily [166]. In another 6-month placebo-controlled RCT in patients initiating allopurinol at a dose of 100 mg od followed by up-titration in 100 mg increments, flares occurred in 33% of patients given colchicine 500 μg bd for flare prophylaxis compared with 77% of those treated with placebo [167]. An investigator-initiated reanalysis of gout flare data from the three phase III trials of febuxostat found that flare prophylaxis for up to 6 months with colchicine 600 μg od or naproxen 250 mg bd, during the initiation of ULT with febuxostat or allopurinol, appeared to provide greater benefit than flare prophylaxis for 8 weeks, with no increase in adverse events [168]. There is little other research evidence to help determine the optimal duration of prophylaxis. A systematic review [125] identified a single RCT comparing three treatment groups given colchicine 1000 μg daily for 3–6, 7–9 and 10–12 months [169]. By 12 months, recurrent acute gout was reported by 54%, 28% and 23%, respectively. Adverse events did not differ between the three groups. However, the risk of bias was high.

Long-term prophylaxis with colchicine or NSAIDs in patients with gout always demands a careful consideration of the overall benefit to risk balance in individual patients, and especially in those with co-morbidities and potential for drug interactions. When using Cox-2 selective or non-selective NSAIDs, the risks of upper GI bleeds and cardiovascular risk should be considered, and gastro-protection with a proton pump inhibitor is recommended. Although usually well tolerated, possible side effects of long-term colchicine include diarrhoea, nausea/vomiting, marrow suppression, myopathy and rhabdomyolysis.

The use of flare prophylaxis is particularly important when ULT is initiated with febuxostat, as the lowest available starting dose in the UK (80 mg) lowers the serum acid level to a greater degree than the starting dose of allopurinol (100 mg), and the risk of precipitating a gout flare is consequently greater [97].

There is no research evidence to support the use of corticosteroids for flare prophylaxis.

IL-1 inhibitors have also been investigated for use for flare prophylaxis [69, 169–172] but none are currently approved for this indication by the EMA or FDA and it is likely that the costs of these biologics will preclude their use for this indication in patients with gout in the UK NHS. In a phase II trial of various doses of canakinumab and colchicine 500 μg od in over 400 patients initiating treatment with allopurinol, the mean number of flares per patient after 4 months was less in the canakinumab-treated patients at all doses >50 mg but there was no evidence of a dose response and there were more infections in the canakinumab-treated patients (18%) than in those given colchicine prophylaxis (12%) [169].

Management points in special groups

Patients with renal insufficiency

CKD and nephrolithiasis are very common in patients with gout. A recent systematic review and meta-analysis of epidemiological and observational studies suggested that the overall prevalence of CKD (stage 3 or greater; GFR < 60 ml/min/1.73 m^2) in patients with gout was 24% compared with 8.5% in the non-gouty population, and the prevalence of self-reported nephrolithiasis was 14% [173]. This presents physicians with important challenges in managing patients with gout, and management of gout in patients with renal impairment has been the subject of two recent systematic reviews and a guideline from the US National Kidney Foundation [174, 175].

For the management of acute gout, the dose of oral colchicine should be reduced in patients with eGFR 10–50 ml/min/1.73 m^2 but is contraindicated in patients with more severe renal impairment (GFR < 10 ml/min/1.73 m^2). High-dose NSAIDs should not be used even in patients with moderate renal impairment [176, 177]. Although the efficacy of corticosteroids in those with CKD has not been evaluated in RCTs [174], clinical experience suggests that they can be effective and safe for managing acute gout in patients with severe renal impairment or in other patients in whom colchicine and NSAIDs cannot be used. Intra-articular triamcinolone hexacetonide (40 mg for large joints, 10–20 mg for smaller joints) is often recommended if only one or two joints are inflamed, or a 7–14-day course of oral prednisolone (30–40 mg tapering to nothing), if multiple joints are involved or if arthrocentesis is not possible.

Guidelines for the use of allopurinol, febuxostat and uricosuric drugs in patients with renal impairment have been discussed following recommendations V, VI and VII for the optimal use of urate-lowering therapies.

Flare prophylaxis with colchicine or NSAIDs in patients with gout and renal insufficiency initiating ULT needs to be undertaken with great caution as the risks of colchicine toxicity, especially myopathy, are increased in patients with renal impairment [178] and NSAIDs can cause acute kidney injury and further impair renal function in patients with CKD [179]. Prophylaxis with low-dosage colchicine, adjusted for renal function, is believed to be a safer option than low-dose NSAIDs [174, 175]. Based on pharmacokinetic data in patients with CKD [180], it is suggested that there is no need for reduction in colchicine dosage (500 μg od or bd) for flare prophylaxis in patients with mild renal insufficiency (eGFR >60 ml/min/1.73 m^2) but the dose should be limited to 500 μg od in those with an eGFR of 30–60 ml/min/1.73 m^2 and to 500 μg

Downloaded from https://academic.oup.com/rheumatology/article/56/7/e1/3855179 by guest on 03 February 2023

every 2–3 days with eGFR 10–30 ml/min/1.73 m^2 [181] and avoided altogether if eGFR <10 ml/min/1.73 m^2. Although it is usually recommended that NSAIDs should be avoided in all patients with renal impairment, a recent systematic review and meta-analysis of observational studies found no evidence of accelerated CKD progression in patients with moderate to severe renal impairment treated with low-dose NSAIDs (OR: 0.96; 95% CI: 0.86, 1.07) [176].

Severe refractory tophaceous gout

Patients with severe symptomatic tophaceous gout in whom hyperuricaemia cannot be controlled with standard ULTs alone, or in combination, should be referred to a rheumatologist. Pegloticase, a polyethylene glycol modified mammalian uricase, can be effective in such patients [182, 183], although not approved by NICE. The drug is administered by i.v. infusion (8 mg in 250 ml normal saline over 2 h) every 2 weeks by physicians with experience and facilities for dealing with infusion reactions, and patients should be pre-treated with antihistamines and steroids to reduce the risk of infusion reactions, in addition to low-dose colchicine or NSAIDs for flare prophylaxis. Despite heavy pegylation, pegloticase is immunogenic. sUA should be measured before each infusion, and treatment discontinued if the sUA is >360 μmol/l as transient responders (about 50%) appear to be at increased risk for infusion reactions and anaphylaxis. Pegloticase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency because of the risk of haemolysis, and extra caution is required in patients with congestive heart failure. Pegloticase has FDA approval and EMA marketing authorization in Europe but has not been approved by NICE or the SMC because of concerns about toxicity and cost. Rasburicase, a recombinant *Aspergillus flavus* uricase that is licensed for the treatment and prophylaxis of tumour lysis syndrome, but not for gout, has also been used successfully in some patients with severe refractory gout [184] despite its greater potential immunogenicity. Prescribers in the UK should be aware of the potential need to obtain approval for an individual funding request before these drugs should be used.

In pregnancy

Apart from patients with familial juvenile hyperuricaemic nephropathy [185], gout is very uncommon in pre-menopausal women and in pregnancy [186] and so data are sparse. Conservative measures including ice are safe for managing acute attacks. NSAIDs can be used in the mid-trimester [187]. Steroids are generally safe to use in pregnancy [188] and the recommendations for lifestyle modifications including the dietary changes discussed previously are also safe.

The safety data for colchicine during pregnancy are largely derived from studies of its use in FMF [189] although there are also some reports of chromosomal damage. High concentrations of colchicine can be found in breast milk and so colchicine is best avoided when breast feeding.

Allopurinol and febuxostat have not been adequately tested during pregnancy. Probenecid was used extensively in the past during antibiotic treatment of infections in pregnant women without any reported fetal toxicity.

Applicability and utility

Statement of potential organizational barriers to introduction

Despite the increasing prevalence of gout and the availability of effective and potentially curative ULT for >50 years, its management remains poor with only 40% of patients with gout ever receiving ULT [1]. Inadequate provision of information to patients [29] has been identified as one of the key barriers [30–32] to effective management of gout. There is preliminary evidence that patient adherence to ULT and lowering of sUA to target levels can be achieved with better provision of information and a package of care based on guideline recommendations [33]. Effective provision of information and monitoring of treatment to achieve target sUA levels requires regular ongoing clinical review. However, anecdotal reports suggest that some secondary care organizations prohibit follow-up of patients with gout, insisting on discharge with a treatment plan to primary care where treatment is known to be suboptimal. Furthermore, although ~20% of people presenting with their first attack will have a second episode within 12 months [190], patients often do not consult for subsequent attacks, so practitioners may not be aware of recurrent attack frequency and the need for ULT, highlighting the case for discussing ULT early in the course of disease.

Potential cost implications for implementation of the guideline

Although there are few cost-effectiveness studies in gout, the guideline takes these into account. The guideline recommends as the first-line ULT allopurinol, which is inexpensive and likely to be tolerated and effective in the vast majority of patients with gout. The cost-effectiveness of febuxostat as a second-line ULT has been established and our guidance for its use concords with its NICE and SMC approval [129, 130, 144, 146]. The guideline does include recommendations for unlicensed or non-NICE-approved use of pegloticase and IL-1 inhibitors although the need to use these drugs is likely to be rare and individual clinicians are advised to consider local arrangements for funding individual funding requests if using these drugs.

Summary of changes in the revised recommendations

This guideline contains several important changes from the 2007 BSR/BHPR guideline [2]. The importance of patient education and provision of information about gout and its treatment are strongly emphasized in the updated guideline (recommendation I for the management of acute attacks, recommendations II and III for the modification of

Downloaded from https://academic.oup.com/rheumatology/article/56/7/e1/3855179 by guest on 03 February 2023

lifestyle and risk factors and recommendation I, II and III for the optimal use of urate-lowering therapies). It is now recommended that an NSAID or colchicine are both drugs of choice for acute gout when there are no contraindications and that the choice of first-line agent should be determined by renal function, co-morbidities and patient preference (recommendation III for the management of acute attacks). Combinations of NSAIDs with corticosteroids or colchicine can be used for acute attacks where response to monotherapy is insufficient (recommendation V for the management of acute attacks), and IL-1 inhibitors may be considered in patients who have not responded adequately to standard treatment (recommendation VI for the management of acute attacks).

The revised guideline emphasizes that all patients with gout should be screened for cardiovascular risk factors and co-morbid conditions such as cigarette smoking, hypertension, diabetes mellitus, dyslipidaemia, obesity and renal disease at least annually and treated appropriately (recommendation V for the modification of lifestyle and risk factors). It is now recommended that that the option of ULT should be explained and offered to all patients with gout as part of their education about the condition and that patients are fully involved in the decision as to when to commence ULT (recommendations I and II for the optimal use of urate-lowering therapies). Although the revised guideline still recommends reduction of sUA with ULT to a target of 300 μmol/l, ULT dose adjustment to the less stringent sUA target of 360 μmol/l is now recommended after some years of successful ULT when tophi have resolved and the patient remains symptom free (recommendation IV for the optimal use of urate-lowering therapies). It is now recommended that in patients with renal impairment the maintenance dose of allopurinol need not be strictly limited according to the creatinine clearance. The starting dose should, however, be low and then carefully increased with smaller increments (50 mg) until the target sUA of 300 μmol/l is reached (recommendation V for the optimal use of urate-lowering therapies). Febuxostat can be used as an alternative second-line xanthine oxidase inhibitor for patients in whom allopurinol is not tolerated or whose renal impairment prevents allopurinol dose escalation sufficient to achieve the therapeutic target (recommendation VI for the optimal use of urate-lowering therapies). For patients with severe symptomatic tophaceous gout in whom hyperuricaemia cannot be controlled with standard ULTs alone, or in combination, treatment with pegloticase can be considered by physicians with experience and facilities for dealing with infusion reactions.

An audit tool is available on the website of the British Society for Rheumatology. Questions for audit and recommendations for future clinical research can be found Supplementary Table S2, available at *Rheumatology online* and in the audit tool.

Funding: No specific funding was received from any bodies in the public, commercial or not-for-profit sectors to carry out the work described in this manuscript.
Disclosure statement: W.Z. reports grants from Arthritis Research UK, Health Technology Assessment, National Institute for Health Research and honoraria for consultations from AstraZenica, Daiichi Sankyo, Biobarica, Hisun and Grunenthal outside the submitted work. M.D. has received honoraria for ad hoc advisory boards relating to osteoarthritis and gout from Ardea Biosciences, AstraZeneca, Nordic Biosciences and Roche; AstraZeneca are funding a Nottingham University investigator-led non-drug study on gout. G.N. was a member of the Independent Disease Monitoring Committee for trials of lesinurad (Ardea/AstraZeneca), and has received honoraria for advisory boards from Gruenenthal and Menarini, and research funding from Menarini for the FAST trial. T.M.M. is or has been principle investigator on trials paid for by Pfizer, Novartis, Ipsen, Teijin and Menarini, received consulting or speakers fees from Pfizer, Novartis, Takeda, Shire and Lundbeck and their department holds research grants from Novartis, Pfizer, Amgen, Ipsen, Teijin and Menarini. Objective. **Existing criteria for the classification of gout have suboptimal sensitivity and/or specificity, and were developed at a time when advanced imaging was not available. The current effort was undertaken to develop new classification criteria for gout.**

Methods. **An international group of investigators, supported by the American College of Rheumatology and the European League Against Rheumatism, conducted a systematic review of the literature on advanced imaging of gout, a diagnostic study in which the presence of monosodium urate monohydrate (MSU) crystals in synovial fluid or tophus was the gold standard, a ranking exercise of paper patient cases, and a multicriterion decision analysis exercise. These data formed the basis for developing the classification criteria, which were tested in an independent data set.**

Results. **The entry criterion for the new classification criteria requires the occurrence of at least 1 episode of peripheral joint or bursal swelling, pain, or tenderness. The presence of MSU crystals in a symptomatic joint/bursa (i.e., synovial fluid) or in a tophus is a sufficient criterion for classification of the subject as having gout, and does not require further scoring. The domains of the new classification criteria include clinical (pattern of joint/bursa involvement, characteristics and time course of symptomatic episodes), laboratory (serum urate, MSU-negative synovial fluid aspirate), and imaging (double-contour sign on ultrasound or urate on dual-energy computed tomography, radiographic gout-related erosion). The sensitivity and specificity of the criteria are high (92% and 89%, respectively).**

Conclusion. **The new classification criteria, developed using a data-driven and decision analytic approach, have excellent performance characteristics and incorporate current state-of-the-art evidence regarding gout.**

Introduction

Gout, which is characterized by deposition of monosodium urate monohydrate (MSU) in synovial fluid and other tissues, is the most common form of inflammatory arthritis, with a prevalence of 3.9% in the US (1), 0.9% in France (2,3), 1.4–2.5% in the UK (4–6), 1.4% in Germany (5), and 3.2% (European ancestry)–6.1% (Maori ancestry) in New Zealand (7). Over the last decade, several new therapies for gout have been approved by regulatory agencies or are being tested (8). The conduct of trials that lead to drug approval, and of observational studies that provide insights into risk factors, genetic associations, and general epidemiology of gout, is critically dependent on appropriate identification of individuals with gout for inclusion in such studies. Classification criteria serve the purpose of enabling standardized assembly of a relatively homogeneous group of individuals with the disease of interest for enrollment into such studies (9).

There are several existing sets of classification criteria or diagnostic rules for gout (10–14), with the most widely used being the 1977 American Rheumatism Association (now the American College of Rheumatology [ACR]) preliminary criteria for the classification of the acute arthritis of primary gout (10). These preliminary criteria were intended for identifying the acute arthritis of gout and not necessarily for intercritical gout, the spectrum of comparator diseases was limited, and physician diagnosis was the gold standard. In a recent study in which the gold standard was MSU crystal status in synovial fluid or nodule aspirate among individuals with a broad range of diagnoses, the sensitivity of existing criteria sets (10–14) ranged from 57.6% to

Phase 1
•Delphi exercise: item generation
•Diagnostic study (SUGAR): test items for inclusion
•Systematic literature review of advanced imaging modalities
Phase 2
•Paper patient cases: ranking exercise
•Consensus meeting: development of domains and categories
•Multi-criterion decision methodology: derivation of weights for each category
Final Criteria
•Defining criteria threshold: i) paper patient exercise; ii) maximization of the sum of sensitivity and specificity in SUGAR development data set
•Testing and comparison of new criteria with existing published criteria: application of criteria to the independent SUGAR test data set

Figure 1. Flow chart of the study process. The major steps taken to develop the new American College of Rheumatology/European League Against Rheumatism criteria for classification of gout are outlined. SUGAR = Study for Updated Gout Classification Criteria.

100% (i.e., 100% with MSU crystal identification as sufficient for classification as gout), whereas the specificity ranged from 34.3% to 86.4%, with no single criteria set having both excellent sensitivity and excellent specificity (15,16). Such findings highlight the need for classification criteria with improved performance characteristics, with higher specificity likely to be favored in order to ensure that individuals enrolled into trials for treatments with unclear efficacy and safety truly have gout.

Accurate classification of gout without crystal documentation for recruitment into studies is also needed, since the majority of cases of gout are managed in primary or acute care settings (17,18), where synovial fluid aspiration and polarizing microscopy are not commonly performed. Additionally, the existing published criteria were developed at a time when advanced imaging modalities, such as ultrasonography or dual-energy computed tomography (DECT), had not been studied; their utility for gout classification in the context of other clinical and laboratory parameters is not known.

To address these issues, an international collaborative working group to develop new classification criteria for gout was convened with the support of the ACR and the European League Against Rheumatism (EULAR) (19). The final results are reported here.

Methods

The major steps taken to develop the new classification criteria are outlined in Figure 1.

Phase 1. To identify factors to be considered for the content of classification criteria for gout, 3 studies were undertaken (Figure 1). First, clinicians with expertise in gout and patients with gout identified factors they believed to discriminate gout from other rheumatic diseases in a Delphi exercise (20). Second, we tested items from this Delphi exercise that were agreed to be potentially discriminatory for gout and items from existing classification criteria in a cross-sectional diagnostic study (Study for Updated Gout Classification Criteria [SUGAR]) (21). Briefly, this study included 983 consecutive subjects (exceeding the recruitment target of 860) who had had joint swelling or a subcutaneous nodule within the previous 2 weeks, either of which was judged to be conceivably due to gout. These subjects were recruited from rheumatology clinics in 16 countries. All subjects were required to undergo aspiration of the symptomatic joint or nodule, with crystal examination performed by a certified observer (21,22), and imaging (ultrasound, radiography). Those who were MSU crystal positive were designated as cases while those who were MSU crystal negative were designated as controls, irrespective of clinical diagnosis. Analyses in the SUGAR study were conducted among two-thirds of the sample (derivation data set; n = 653); the other one-third (n = 330) were analyzed as the validation data set for the final criteria. Third, we conducted a systematic literature review of advanced imaging modalities for classifying gout (23).

Phase 2. *Rationale.* It was recognized that the SUGAR study and the imaging review may have some limitations. The SUGAR study might have been prone to selection bias as MSU crystal positivity was required in order for a subject to be considered a case; this may have introduced bias toward larger joints, more severe disease, and/or tophaceous disease. In addition, subjects were recruited from rheumatology clinics, which may have contributed to spectrum bias since most patients with gout are seen in primary care settings. The systematic literature review of imaging was limited by the relative paucity of published data, and comparator diseases included were limited. Thus, Phase 2 was envisioned as a complementa-

ry phase that would incorporate the data derived in Phase 1 with clinical expertise to address a broader spectrum of clinical gout.

Approach to identifying domains and categories. In Phase 2, an international panel of expert rheumatologists and primary care physicians used a multicriterion decision analytic consensus methodology, informed by data generated in Phase 1, to determine the factors that best discriminated gout from other rheumatic diseases that could conceivably be considered in the differential diagnosis. Such an approach would lead to expert-derived, data-informed weighting of discriminating factors. The specific methods are described below.

Rheumatologists and general internists with an interest in gout submitted paper patient cases of patients for whom gout was in the differential diagnosis, using standardized data collection forms. A subset of 30 paper patient cases was selected to represent a broad spectrum of the probability of gout. Prior to the in-person expert panel meeting, panel members were given the data from Phase 1 to review, and they were asked to rank-order the 30 paper patient cases from lowest to highest probability of having gout.

At the in-person expert panel meeting, held over 2 days (June 9–10, 2014 in Paris, France in advance of the EULAR Congress), 3 concepts were agreed upon a priori. First, the task was to develop criteria that would enable standardized assembly of a well-defined, relatively homogeneous group of subjects representative of persons with gout, for entry into observational studies or clinical trials. Such criteria are not intended to capture *all* possible patients, but rather to capture the great majority of patients with shared key features of gout. Second, the classification was to apply to the patient's total disease experience, not to classify individual symptomatic episodes. Third, elements of the criteria could be accrued over time such that individuals could fulfill criteria at a later time point even if they did not at the initial assessment.

Review of the Phase 1 data and the paper patient case ranking exercise formed the basis for in-depth discussion to identify key features that were pertinent to the probability of gout. Based on these key features, initial formulation of potential criteria was developed, with consideration of entry, sufficient, and exclusion criteria, and more precise definition of domains and their categories. Decisions regarding domains and their categories were supported, where possible, by Phase 1 data and/or any other available published evidence.

Approach to assigning relative weights to domains and categories. Once the Paris panel agreed upon preliminary domains and categories, the members undertook a discrete-choice conjoint analysis exercise guided by an experienced facilitator (RPN) and aided by a rheumatologist with experience in the process (TN), similar to that used for other classification criteria (e.g., rheumatoid arthritis, systemic sclerosis) (24–29). Specifically, we used a computer software program, 1000Minds (www.1000minds.com), which utilizes decision science theory and computer adaptive technology to carry out a series of discrete forced-choice experiments through pairwise ranking of alternatives that lead to quantified weights of each domain and each category within the domains (28,30). Briefly, the expert panel was presented with a series of paired scenarios, each of which contained the same 2 domains, but with different combination of the domains' categories grouped together in each scenario. The panel was instructed to assume that all other parameters were equivalent between the 2 patients represented by the scenarios. The distribution of votes (percent who voted for "A," "B," or "equal probability") was presented for each pair of scenarios after each vote. Discussion occurred after each vote, with re-voting as necessary. Consensus was considered to have been achieved when all participants either indicated complete agreement as to which scenario represented a higher probability of gout, or indicated that they could accept the majority opinion.

Relative weights were derived with the decision analytic software, based on the voting results of the discrete-choice scenarios and refined by each successive result. Upon completion of the voting exercise, the relative weights for each category and domain, and the face validity of the resulting rank order of 10 paper patient cases, were reviewed.

After the in-person meeting, minor scoring simplifications were incorporated and pretested in the SUGAR derivation data set (i.e., the original two-thirds sample analyzed in Phase 1). A cutoff score that maximized the sum of sensitivity and specificity was determined, to examine misclassification.

Approach to developing final criteria scoring. The raw weights from the scoring system were simplified into whole numbers, with performance characteristics assessed for each simplification.

Approach to defining criteria threshold for classifying gout. The original 30 paper patient cases (except for 3 with demonstrated MSU crystals), in addition to 20 subjects from the SUGAR study analyzed in Phase 1 who had unique scores close to the cutoff score derived as described above, were used for a threshold identification exercise. For these 20 subjects, if synovial fluid microscopy had failed to show MSU crystals, this information was provided. Otherwise, the results of synovial fluid examination were recorded as "not done." This information was not made known to the expert panel. These cases were arranged according to their score in descending order. In an online exercise, the expert panel indicated whether they would classify the patient as having gout with sufficient confidence to feel comfortable enrolling that patient into a Phase 3 trial of a new urate-lowering agent.

Testing of the new gout classification criteria and comparison with existing published criteria. The final criteria set was evaluated in the SUGAR validation data set (i.e., the one-third of the data set that had not been used for any analyses to date [n = 330]); the purpose of this was to enable validation of the newly developed criteria in an independent data set. A secondary analysis was conducted to evaluate how the criteria would perform if only clinical parameters were available (i.e., without MSU determination or imaging). The performance characteristics of the new criteria were compared with those of existing published criteria using logistic regression.

Results

The expert panel (n = 20) comprised 19 physicians with a clinical and/or research interest in gout (17 clinical rheumatologists and 2 primary care physicians) and an epidemiologist/biostatistician; 9 members of the panel were from the US, 8 from Europe, 2 from New Zealand, and 1 from Mexico. One hundred thirty-three paper cases were submitted by the expert panel and 79 clinical rheumatologists and general internists.

Table 1. Definitions and considerations for each domain*

Domain†	Definitions and special considerations
1. Pattern of joint/bursa involvement during symptomatic episode(s) ever Categories are defined as per the description of the distribution of joints involved	Distribution of joints: involvement (ever) of i) Joint(s) or bursa(e) other than ankle, midfoot or first metatarsophalangeal (MTP) joint (or their involvement only as part of a polyarticular presentation) ii) Ankle or midfoot joint(s) as monoarticular or part of an oligoarticular presentation without first MTP joint involvement iii) MTP joint involvement as monoarticular or part of an oligoarticular presentation
2. Characteristics of symptomatic episode(s) ever Categories are defined as No characteristics present 1 characteristic present 2 characteristics present 3 characteristics present	Characteristics to consider: presence (ever) of i) Great difficulty with walking or inability to use the affected joint(s) during a symptomatic episode ever (patient-reported) ii) Can't bear touch or pressure to the affected joint during a symptomatic episode ever (patient-reported) iii) Erythema overlying affected joint during a symptomatic episode ever (patient-reported or physician-observed)
3. Time course of symptomatic episode(s) ever Categories are defined as No typical episodes 1 typical episode Recurrent typical episodes	"Typical symptomatic episode": presence (ever) of >2 of the following, irrespective of antiinflammatory treatment i) Time to maximal pain <24 hours ii) Resolution of symptoms in ≤14 days iii) Complete resolution (to baseline level) between symptomatic episodes
4. Clinical evidence of tophus Categories are defined as Present Absent	Appearance: draining or chalk-like subcutaneous nodule under transparent skin, often with overlying vascularity (Figure 2) Location: classic locations—joints, ears, olecranon bursae, finger pads, tendons (e.g., Achilles)
5. Serum urate level, off-treatment Categories are defined as <4 mg/dl (0.24 mmoles/liter) 4–<6 mg/dl (0.24–<0.36 mmoles/liter) 6–<8 mg/dl (0.36–<0.48 mmoles/liter) 8–<10 mg/dl (0.48–<0.60 mmoles/liter) ≥10 mg/dl (≥0.60 mmoles/liter)	Which serum urate measurement to use: highest reading on record, off urate-lowering therapy Special considerations: Ideally, the serum urate level should be scored if tested at a time when the patient was not receiving urate-lowering therapy and it was >4 weeks from the start of an episode; *if* practicable, retest under those conditions. If serum urate level is ≥10 mg/dl, no need to retest.
6. Synovial fluid analysis Categories are defined as MSU negative Not done	Location: symptomatic (ever) joint or bursa Special considerations: Assessment should be performed by a trained observer. Note: MSU positive is a sufficient criterion.
7. Imaging evidence of urate deposition Categories are defined as Absent *or* not done Present (either modality)	Modality: ultrasound or DECT Appearance: double-contour sign on ultrasound (Figure 3A)‡ *or* urate deposition on DECT (Figure 3B)§ Location: symptomatic (ever) joint or bursa
8. Imaging evidence of gout-related joint damage Categories are defined as Absent *or* not done Present	Modality: radiography Appearance of gout-related erosion: cortical break with sclerotic margin and overhanging edge; excludes gull wing appearance (Figure 3C) Location: radiograph of hands and/or feet; excludes distal interphalangeal joints

* Symptomatic (ever) refers to pain and/or swelling.
† Categories within each domain are hierarchical; if a subject fulfills more than 1 category, the highest category should be selected.
‡ A false-positive double-contour sign (artifact) may appear at the cartilage surface, but should disappear with a change in the insonation angle of the probe (31,32).
§ Images should be acquired using a dual-energy computed tomography (DECT) scanner, with data acquired at 80 kV and 140 kV and analyzed using gout-specific software with a 2-material decomposition algorithm that color-codes urate (33). A positive scan result is defined as the presence of color-coded urate at articular or periarticular sites. Nailbed, submillimeter, skin, motion, beam hardening, and vascular artifacts should not be interpreted as DECT evidence of urate deposition (34).

Based on review of the Phase 1 data and the ranking exercise with the 30 cases representing low to high probability of gout, initial key factors that were identified as being important for classifying gout were presence of MSU crystals, pattern of joint involvement, intensity of symptomatic episodes, time to maximal pain and to resolution, episodic nature of symptoms, presence of clinical tophus, level of serum urate, imaging features, response to treatment, family history, and risk factors or associated comorbidities. The last 3 factors were not considered further as they are not features of gout itself despite their association with gout, and inclusion of risk factors or

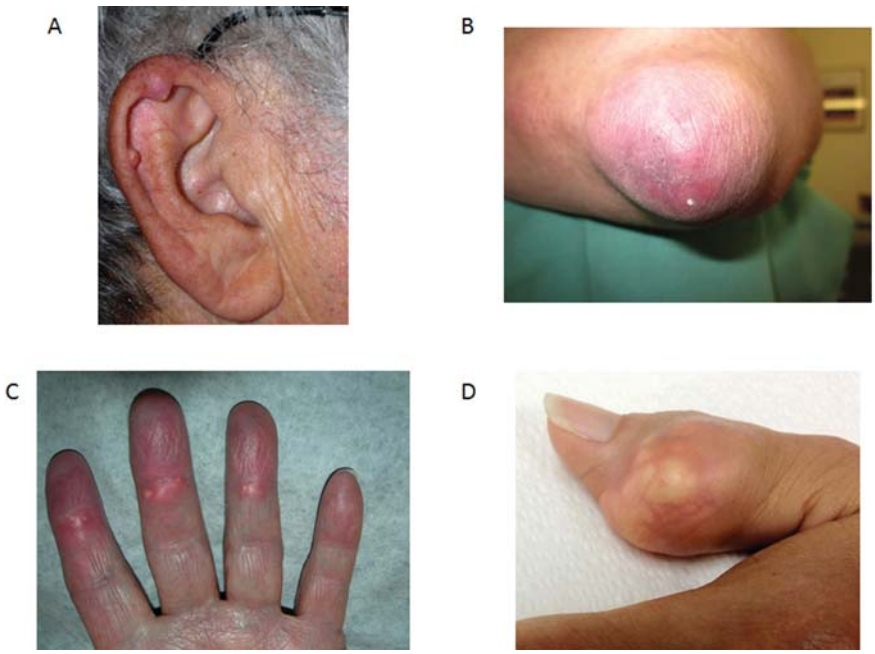

Figure 2. Examples of tophus. The tophus is defined as a draining or chalk-like subcutaneous nodule under transparent skin, often with overlying vascularity. Typical locations are the ear (**A**), the elbow (olecranon bursa) (**B**), and the finger pulps (**C** and **D**). Note the overlying vascularity in **D**.

comorbidities in the definition of gout would preclude future studies evaluating their association with gout.

Entry, sufficient, and exclusion criteria. Before embarking upon defining domains and domain categories (the classification criteria), we defined entry, sufficient, and exclusion criteria. The entry criteria were intended to be used to identify the relevant patient population to whom the classification criteria would be applied. Sufficient criteria were intended to define features such as a gold standard that alone could classify gout without further need to apply the classification criteria scoring system. Exclusion criteria were intended to define individuals in whom gout could be ruled out (among those who met entry criteria) and to whom the classification criteria should not be further applied. The expert panel agreed that these classification criteria should be applicable only to people with symptomatic disease because the prognosis of asymptomatic disease is presently not well delineated in the literature, and to enable categorization based on features of symptomatic episodes. The *entry criterion* was defined as the occurrence of at least 1 episode of swelling, pain, or tenderness in a peripheral joint or bursa. The *sufficient criterion* was defined as the presence of MSU crystals in a symptomatic joint or bursa (i.e., in synovial fluid) or tophus as observed by a trained examiner. The panel agreed that there would be no exclusion criteria because gout can often coexist with other diseases and because synovial fluid microscopy can sometimes fail to disclose MSU crystals in patients with gout for technical, sampling, or treatment reasons.

Domains and categories. Based on the key features identified initially, Phase 1 data, and available published literature, and with a defined population to whom the criteria would apply, the expert panel further developed the pertinent domains and their respective categories in an iterative process. The expert panel aimed to define relevant clinical and imaging parameters to be as specific as possible for gout.

The domains included clinical parameters (numbers 1–4), laboratory parameters (numbers 5 and 6), and imaging parameters (numbers 7 and 8). The specific domains and their respective definitions are summarized in Table 1. The domains were designed to be scored based on the totality of the subjects' symptomatic disease experience. All of the categories within domains are hierarchical and mutually exclusive, such that if both a higher and a lower category have been fulfilled at different points in time, the higher one should be scored; the highest categories are listed last within each domain.

Symptomatic episodes were defined as those in which there was swelling, pain, or tenderness in a peripheral joint or bursa. For the pattern of joint involvement, it was agreed that first metatarsophalan-

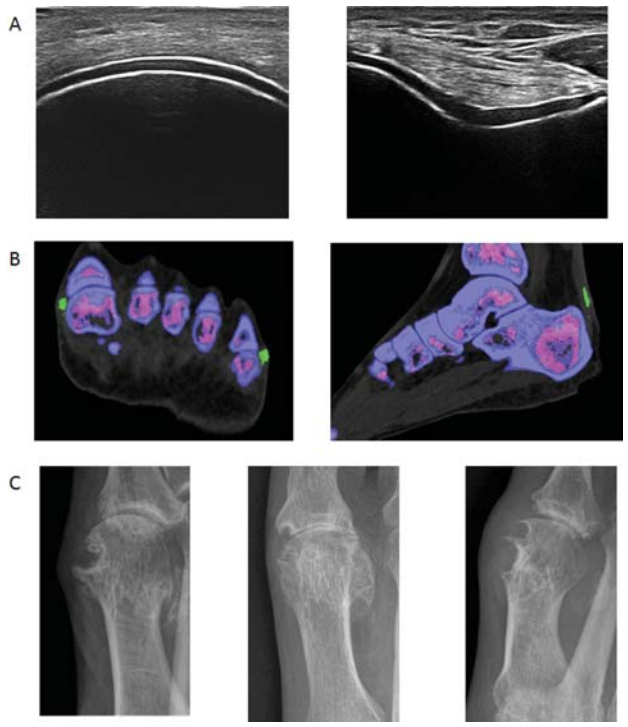

Figure 3. Examples of imaging features included in the classification criteria. **A,** Double-contour sign seen on ultrasonography. Left panel shows a longitudinal ultrasound image of the femoral articular cartilage; right panel shows a transverse ultrasound image of the femoral articular cartilage. Both images show hyperechoic enhancement over the surface of the hyaline cartilage (images kindly provided by Dr. Esperanza Naredo, Hospital Universitario Gregorio Marañon, Madrid, Spain). **B,** Urate deposition seen on dual-energy computed tomography. Left panel shows urate deposition at the first and fifth metatarsophalangeal joints; right panel shows urate deposition within the Achilles tendon. **C,** Erosion, defined as a cortical break with sclerotic margin and overhanging edge, seen on conventional radiography of the first metatarsophalangeal joint.

geal joint, ankle, or midfoot involvement as part of a polyarticular presentation, though possible in gout, was not specific enough for gout since that pattern could be seen commonly in other disorders such as rheumatoid arthritis. The time course of symptomatic episodes was to be considered irrespective of antiinflammatory treatment. For clinical tophus, a precise definition in terms of appearance and location was developed to assist in differentiation from other subcutaneous nodules that may be confused with tophi. Examples of clinically evident tophi are provided in Figure 2. Serum urate was considered a mandatory element of the classification criteria scoring system (i.e., the score cannot be computed without a serum urate value). For the synovial fluid domain, the fluid must be aspirated from a symptomatic (ever) joint or bursa, and assessed by a trained observer. If the synovial fluid aspirate was MSU positive, the individual would have been classified as having gout under the sufficient criterion without evaluating the rest of the classification criteria.

For imaging evidence of urate deposition, the imaging modalities with sufficient published data and investigator experience to support their utility in identifying urate deposition accurately were ultrasound and DECT. Magnetic resonance imaging and conventional CT did not have sufficient published data or investigator experience to support their consideration. For ultrasound evidence of urate deposition, the required finding is the double-contour sign (DCS), defined as hyperechoic irregular enhancement over the surface of the hyaline cartilage that is independent of the insonation angle of the ultrasound beam (note: false-positive DCS [artifact] may appear at the cartilage surface but should disappear with a change in the insonation angle of the probe) (31,32). Examples of gout-related DCS are provided in Figure 3. For DECT, urate deposition is defined as the presence of color-coded urate at articular or periarticular sites (Figure 3). Images should be acquired using a DECT scanner, with data acquired at 80 kV and 140 kV and analyzed using gout-specific software with a 2-material decomposition algorithm that color-codes urate (33). A positive scan result is defined as the presence of color-coded urate at articular or periarticular sites. Nailbed, submillimeter size, skin, motion, beam hardening, and vascular artifacts should not be interpreted as DECT evidence of urate deposition (34). The scoring of this imaging domain is applicable only to a symptomatic (ever) joint or bursa (i.e., swelling, pain, or tenderness), and is scored as present on either modality, or absent/not done (i.e., neither modality was performed). That is, if *either* imaging modality demonstrates the required finding, then urate deposition is considered to be present.

Finally, imaging evidence of gout-related joint damage is to be scored on the basis of conventional radiography of the hands and/or feet demonstrating at least 1 gout-related erosion, which is defined as a cortical break with sclerotic margin and overhanging edge (Figure 3). The distal interphalangeal joints and gull wing appearance should be excluded from this evaluation since they can occur in osteoarthritis.

Assigning relative weights to domains and categories. Once the domains and categories were defined, the expert panel undertook a series of discrete-choice experiments. This work resulted in weights being assigned to each category and domain, such that the highest category of each domain summed to a total of 100%. Any necessary revisions to the categories were

Table 2. The ACR/EULAR gout classification criteria*

	Categories	Score
Step 1: Entry criterion (only apply criteria below to those meeting this entry criterion)	At least 1 episode of swelling, pain, or tenderness in a peripheral joint or bursa	
Step 2: Sufficient criterion (if met, can classify as gout without applying criteria below)	Presence of MSU crystals in a symptomatic joint or bursa (i.e., in synovial fluid) or tophus	
Step 3: Criteria (to be used if sufficient criterion not met)		
Clinical		
Pattern of joint/bursa involvement during symptomatic episode(s) ever†	Ankle *or* midfoot (as part of monoarticular or oligoarticular episode without involvement of the first metatarsophalangeal joint	1
	Involvement of the first metatarsophalangeal joint (as part of monoarticular or oligoarticular episode)	2
Characteristics of symptomatic episode(s) ever		
• Erythema overlying affected joint (patient- reported or physician-observed)	One characteristic	1
• Can't bear touch or pressure to affected joint	Two characteristics	2
• Great difficulty with walking or inability to use affected joint	Three characteristics	3
Time course of episode(s) ever		
Presence (ever) of ≥2, irrespective of antiinflammatory treatment:		
• Time to maximal pain <24 hours	One typical episode	1
• Resolution of symptoms in ≤14 days	Recurrent typical episodes	2
• Complete resolution (to baseline level) between symptomatic episodes		
Clinical evidence of tophus (Figure 2)		
Draining or chalk-like subcutaneous nodule under transparent skin, often with overlying vascularity, located in typical locations: joints, ears, olecranon bursae, finger pads, tendons (e.g., Achilles)	Present	4
Laboratory		
Serum urate: Measured by uricase method.		
Ideally should be scored at a time when the patient was not receiving urate-lowering treatment and it was >4 weeks from the start of an episode (i.e., during intercritical period); *if* practicable, retest under those conditions. The highest value irrespective of timing should be scored.	<4 mg/dl (<0.24 mmoles/liter)‡	−4
	6–8 mg/dl (0.36–<0.48 mmoles/liter)	2
	8–<10 mg/dl (0.48–<0.60 mmoles/liter)	3
	≥10 mg/dl (≥0.60 mmoles/liter)	4
Synovial fluid analysis of a symptomatic (ever) joint or bursa (should be assessed by a trained observer)§	MSU negative	−2
Imaging (Figure 3)¶		
Imaging evidence of urate deposition in symptomatic (ever) joint or bursa: ultrasound evidence of double-contour sign# *or* DECT demonstrating urate deposition**	Present (either modality)	4
Imaging evidence of gout-related joint damage: conventional radiography of the hands and/or feet demonstrates at least 1 erosion††	Present	4

* A web-based calculator can be accessed at: http://goutclassificationcalculator.auckland.ac.nz, and through the American College of Rheumatology (ACR) and European League Against Rheumatism (EULAR) web sites.

† Symptomatic episodes are periods of symptoms that include any swelling, pain, and/or tenderness in a peripheral joint or bursa.

‡ If serum urate level is <4 mg/dl (<0.24 mmoles/liter), *subtract 4 points*; if serum urate level is ≥4−<6 mg/dl (≥0.24−<0.36 mmoles/liter), score this item as 0.

§ If polarizing microscopy of synovial fluid from a symptomatic (ever) joint or bursa by a trained examiner fails to show monosodium urate monohydrate (MSU) crystals, *subtract 2 points*. If synovial fluid was not assessed, score this item as 0.

¶ If imaging is not available, score these items as 0.

Hyperechoic irregular enhancement over the surface of the hyaline cartilage that is independent of the insonation angle of the ultrasound beam (note: false-positive double-contour sign [artifact] may appear at the cartilage surface but should disappear with a change in the insonation angle of the probe) (31,32).

** Presence of color-coded urate at articular or periarticular sites. Images should be acquired using a dual-energy computed tomography (DECT) scanner, with data acquired at 80 kV and 140 kV and analyzed using gout-specific software with a 2-material decomposition algorithm that color-codes urate (33). A positive scan is defined as the presence of color-coded urate at articular or periarticular sites. Nailbed, submillimeter, skin, motion, beam hardening, and vascular artifacts should not be interpreted as DECT evidence of urate deposition (34).

†† Erosion is defined as a cortical break with sclerotic margin and overhanging edge, excluding distal interphalangeal joints and gull wing appearance.

Table 3. Performance of the gout classification criteria in the Study for Updated Gout Classification Criteria validation data set, in comparison with existing published criteria

Criteria set (ref.)	Area under the curve*	Sensitivity at published threshold	Specificity at published threshold

† Without synovial fluid microscopy or imaging.
‡ $P < 0.05$ versus the ACR/EULAR criteria.
§ The Netherlands criteria set was intended as a diagnostic aid, and has 2 possible cutoffs (see Supplementary Table 1, on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.39254/abstract); we used the higher cutoff for these analyses because such a score is deemed to suggest gout.

made with subsequent repetition of the discrete-choice experiments after any such changes.

A sample of 10 paper patient cases (from among the original 30 paper cases) was scored and rank-ordered with this preliminary scoring system. The cases were accurately ranked with reference to the expert panel's premeeting rankings, lending face validity to this preliminary scoring system. The scoring was also repeated without the imaging domains, which resulted in little change in the rank-ordering. Correlation between premeeting mean ranking and the initial scoring system ranking was high ($r^2 = 0.71$).

Defining criteria threshold for classifying gout. Using a cutoff score that maximized the sum of sensitivity and specificity from the SUGAR data, the percentage of false-negatives and false-positives was 13.9% and 10.5%, respectively. Next, the expert panel performed a threshold identification exercise designed to assess the members' willingness to enroll 47 paper cases, based on having sufficient confidence that the individual has gout, into a Phase 3 randomized clinical trial of a new urate-lowering agent with unclear efficacy and safety. The score at which the majority considered an individual as having gout or not fell at the same threshold as that identified as the cutoff score that maximized the sum of sensitivity and specificity.

Final criteria scoring. With face validity of the initial scoring system confirmed and a threshold identified, the raw relative weights of the domain categories and the threshold score were rescaled and rounded into whole numbers to make the scoring system as simple as possible, while retaining the relative weighting produced by the expert panel. The maximum possible score in the final criteria is 23. A threshold score of ≥8 classifies an individual as having gout.

A unique aspect of the new classification criteria is that there are 2 categories that elicit *negative* scores. Specifically, if the synovial fluid is MSU negative, *2 points are subtracted* from the total score. Similarly, if the serum urate level is <4 mg/dl (<0.24 mmoles/liter), *4 points are subtracted* from the total score. This approach was taken to emphasize that these findings reduce the probability of gout. The lowest category in each domain has a score of 0 and is therefore not explicitly depicted in the final criteria table; however, for serum urate level, the category that receives a score of 0 is 4−<6 mg/dl (0.24−<0.36 mmoles/liter). If imaging is not performed, those categories are also scored as 0. The final criteria are presented in Table 2. A web-based calculator can be accessed at http://goutclassificationcalculator.auckland.ac.nz, as well as through the ACR and EULAR web sites.

Results of testing of the new gout classification criteria and comparison with existing published criteria. In the SUGAR validation data set (n = 330), the sensitivity of the new classification criteria was 0.92, and specificity was 0.89 (Table 3). The performance of the criteria was also tested using only clinical parameters, i.e., without MSU results, scored as 0 (unknown/not done) and without imaging (i.e., radiographic, ultrasound, or DECT imaging) results, scored as 0; this latter

scoring was in keeping with similar weighting being given to imaging studies that were negative versus not being performed in the discrete-choice experiments. In this setting, the sensitivity and specificity were 0.85 and 0.78.

When compared with existing published criteria (using their respective published thresholds), the new classification criteria performed well. For some existing criteria sets, presence of MSU crystals alone is sufficient to fulfill criteria; they are therefore 100% sensitive by definition. The new gout classification criteria also have MSU positivity as a sufficient criterion for classification, but the criteria set was not assessed in that regard, to avoid circularity. When the new classification criteria set was compared in its complete form (i.e., incorporating imaging and MSU data) with other published "full" criteria, some existing criteria had higher sensitivity, but all had lower specificity (Table 3). Additionally, for the clinical-parameters-only version of the new criteria, the sensitivity was better than that of all but 1 of the other clinical-only criteria sets, and the specificity was similar or better. The new gout classification criteria therefore performed well in both the "full" form and the "clinical-only" form.

Discussion

The new ACR/EULAR gout classification criteria represent an international collaborative effort that incorporates the latest published evidence on imaging modalities, a data-driven approach with MSU identification as a gold standard to reference key features, and a decision analytic approach to inform the weighting of the scoring system. This classification criteria set will enable a standardized approach to identifying a relatively homogeneous group of individuals who have the clinical entity of gout for enrollment into studies. The criteria permit characterization of an individual as having gout regardless of whether he or she is currently experiencing an acute symptomatic episode and regardless of any comorbidities. The new classification criteria have superior performance characteristics, with high sensitivity and improved specificity compared with previously published criteria. Arguably, specificity (leading to high positive predictive value) is of critical importance in most clinical studies since investigators need to have confidence that individuals who are enrolled in a study truly have the condition of interest.

Gout is unlike other rheumatic diseases in that a gold standard assessment is available, i.e., MSU crystal positivity. While this gold standard has high specificity, its feasibility and sensitivity may be inadequate, because of difficulty with aspiration of joints (particularly small ones) and/or examination of the sample under polarizing microscopy. Thus, although MSU crystal results are extremely helpful when positive, they are not a feasible universal standard, particularly because many potential study subjects are likely to be recruited from nonrheumatology settings. We aimed to develop a new set of criteria that could be flexible enough to enable accurate classification of gout regardless of MSU status; a clinical-only version can be considered for use in settings in which synovial fluid or tophus aspiration is not feasible. Nonetheless, in recognition of its gold standard status, the expert panel set the presence of MSU crystal positivity in a symptomatic joint or bursa as sufficient for classifying an individual as having gout. It should be recognized that classification criteria are not intended for use in making a diagnosis in a clinical setting (35). Thus, in clinical practice, joint or tophus aspiration remains an essential component of establishing a diagnosis of gout.

As with most diseases, there is a gradient of probability of truly having the disease based on signs and symptoms. The threshold chosen for this classification criteria set yielded the best combination of sensitivity and specificity. While for certain purposes a higher sensitivity (lower score) may be preferable (e.g., general population survey to determine the public health burden of gout for resource planning), a higher specificity (higher score) may be desirable for others (e.g., genetic association studies in which accurate phenotyping is critical). Furthermore, classification criteria are not intended to characterize the severity of disease, but only its presence. Additionally, classification criteria should be applied only to the intended population—those who meet the entry criteria. Performance characteristics of any classification criteria set will necessarily be altered if the criteria are applied to those other than the intended population.

A limitation of our current effort is that there is still a relative paucity of data and of clinical experience to fully test advanced imaging data empirically. As more studies are published, there may be additional imaging signs and/or modalities found to have sufficient specificity for gout that could be incorporated into future criteria. We also realized that some investigators may not have access to imaging and therefore aimed to develop criteria that would still perform well in the absence of imaging data. In the discrete-choice experiments, the lack of imaging data was weighted the same as for studies performed with negative results, supporting the validity of using the scoring system in the absence of imaging data. We did not address asymptomatic hyperuricemia, since the purpose of classification criteria is to identify individuals with a clinical entity for clinical stud-

ies. There is certainly an interest in studying asymptomatic hyperuricemia, but this was beyond the scope of the current activity; the expert panel agreed that its charge was to classify individuals with symptomatic disease as evidence of a clinical condition. The present criteria set represents an attempt to optimize both sensitivity and specificity for enrollment into trials and prospective epidemiologic studies. Further testing of the criteria in additional samples, particularly in settings from which individuals with gout are likely to be recruited (e.g., primary care), and other study types, is warranted.

This study provides a number of insights relating to the likelihood of gout. First, the clinical picture of gout as an episodic disease with stereotypical features and a predilection for lower-extremity joints, particularly the first metatarsophalangeal joint, was captured in the SUGAR study, despite concerns that the study design might lead to selection bias. Second, there were certain conditions that strongly reduced the likelihood of gout: synovial fluid from a symptomatic joint or bursa that was negative for MSU crystals, and a serum urate level of $<$4 mg/dl (0.24 mmoles/liter). While such findings would not necessarily rule out gout, they were weighted in the discrete-choice experiments such that they lower the probability of gout. Third, both the SUGAR subjects and the paper patient cases were derived from a large international pool, supporting generalizability of these criteria. Finally, advanced imaging modalities have been incorporated into classification criteria for gout for the first time.

In summary, the 2015 ACR/EULAR classification criteria for gout represent an advance over previous criteria, with improved performance characteristics and incorporation of newer imaging modalities. These criteria may be considered as inclusion criteria for future studies of clinical gout.

ACKNOWLEDGMENTS

We are grateful to the following investigators for contributing additional paper patient cases: Drs. Everardo Alvarez Hernandez, Ruben Burgos, Geraldo Castelar, Marco Cimmino, Tony Dowell, Angelo Gaffo, Rebecca Grainger, Leslie Harrold, Phillip Helliwell, Changtsai Lin, Worawit Louthrenoo, Claudia Schainberg, Naomi Schlesinger, Carlos Scire, Ole Slot, Lisa Stamp, Robert Terkeltaub, Harald Vonkeman, Zeng Xuejun. We would like to thank Dr. Thomas Bardin for participating in ranking of the paper cases. We would like to acknowledge and thank Dr. Esperanza Naredo for her advice regarding standardization of the ultrasound definition of double-contour sign. We are also grateful to the following additional investigators who collected data for the SUGAR study: Drs. Lorenzo Cavagna, Jiunn-Horng Chen, Yi-Hsing Chen, Yin-Yi Chou, Hang-Korng Ea, Maxim Eliseev, Martijn Gerritsen, Matthijs Janssen, Juris Lazovskis, Geraldine McCarthy, Francisca Sivera, Ana Beatriz Vargas-Santos, Till Uhlig, Douglas White, and all of the authors of the SUGAR study (full list in ref. 21). We would like to acknowledge and thank Ian Sayer (Application Specialist, Information Services, Faculty of Medical and Health Sciences, University of Auckland, Auckland, New Zealand) for his work on developing the gout classification calculator web page.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Dr. Neogi had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide guidance for particular patterns of practice and not to dictate the care of a particular patient. The ACR considers adherence to these guidelines and recommendations to be voluntary, with the ultimate determination regarding their application to be made by the physician in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed or endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice.

The American College of Rheumatology is an independent, professional, medical and scientific society which does not guarantee, warrant, or endorse any commercial product or service.

Introduction

Gout is a disorder that manifests as a spectrum of clinical and pathologic features built on a foundation of an excess body burden of uric acid, manifested in part by hyperuricemia, which is variably defined as a serum urate level greater than either 6.8 or 7.0 mg/dl (1,2). Tissue deposition of monosodium urate monohydrate crystals in supersaturated extracellular fluids of the joint, and certain other

Supported by a research grant from the American College of Rheumatology and by the National Institute of Arthritis and Musculoskeletal and Skin Diseases, NIH (grant K24-AR-063120).

Significance & Innovations

- Patient education on diet, lifestyle, treatment objectives, and management of comorbidities is a recommended core therapeutic measure in gout.
- Xanthine oxidase inhibitor (XOI) therapy with either allopurinol or febuxostat is recommended as the first-line pharmacologic urate-lowering therapy (ULT) approach in gout.
- Serum urate level should be lowered sufficiently to durably improve signs and symptoms of gout, with the target <6 mg/dl at a minimum, and often <5 mg/dl.
- The starting dosage of allopurinol should be no greater than 100 mg/day and less than that in moderate to severe chronic kidney disease (CKD), followed by gradual upward titration of the maintenance dose, which can exceed 300 mg daily even in patients with CKD.
- Prior to initiation of allopurinol, rapid polymerase chain reaction–based HLA–B*5801 screening should be considered as a risk management component in subpopulations where both the HLA–B*5801 allele frequency is elevated and the HLA–B*5801–positive subjects have a very high hazard ratio ("high risk") for severe allopurinol hypersensitivity reaction (e.g., Koreans with stage 3 or worse CKD and all those of Han Chinese and Thai descent).
- Combination oral ULT with 1 XOI agent and 1 uricosuric agent is appropriate when the serum urate target has not been met by appropriate dosing of an XOI.
- Pegloticase is appropriate for patients with severe gout disease burden and refractoriness to, or intolerance of, appropriately dosed oral ULT options.

sites, mediates most of the clinical and pathologic features of gout. Typically, the disease initially presents as acute episodic arthritis. Gout also can manifest as chronic arthritis of 1 or more joints (1,2). Tophi, mainly found in articular, periarticular, bursal, bone, auricular, and cutaneous tissues, are a pathognomonic feature of gout, and are detectable by physical examination and/or by imaging approaches and pathology examination (3–5). Renal manifestations of gout include urolithiasis, typically occurring with an acidic urine pH (1,2). Chronic interstitial nephropathy, mediated by monosodium urate monohydrate crystal deposition in the renal medulla, can occur in severe disease, but is currently considered to be an uncommon clinical manifestation of gout.

Gout is one of the most common rheumatic diseases of adulthood, with a self-reported prevalence in the US recently estimated at 3.9% of adults (~8.3 million people) (6). The prevalence of gout has risen in many countries (e.g., New Zealand) and especially in the US over the last few decades, mediated by factors such as an increased prevalence of comorbidities that promote hyperuricemia, including hypertension, obesity, metabolic syndrome, type 2 diabetes mellitus, and chronic kidney disease (CKD) (7–10). Other factors in the rising prevalence of gout include certain dietary trends and widespread prescriptions of thiazide and loop diuretics for cardiovascular diseases (11). Many gout patients, including the growing subset of elderly patients affected with gout, have complex comorbidities and medication profiles that complicate overall management (12). Long-term morbidity and impairment of

Drs. Dinesh Khanna, FitzGerald, and Puja P. Khanna contributed equally to this work.

Dr. Dinesh Khanna has received consultant fees, speaking fees, and/or honoraria (less than $10,000 each) from Novartis and Ardea and (more than $10,000 each) from Takeda and Savient, and has served as a paid investment consultant for Guidepoint. Dr. Puja P. Khanna has received speaking fees (less than $10,000) from Novartis and (more than $10,000) from Takeda, and has served on the advisory board for Novartis. Dr. Pillinger has received speaking fees and/or honoraria (less than $10,000 each) from the RA Investigator Network, NY Downtown Hospital, Winthrop Hospital, and Einstein College of Medicine. Dr. Perez-Ruiz has received consultant fees, speaking fees, and/or honoraria (less than $10,000 each) from Novartis, Menarini, and Savient, and (more than $10,000) from Ardea. Dr. Lioté has received consultant fees, speaking fees, and/or honoraria (less than $10,000 each) from Novartis Global, Novartis France, and Ipsen, and has served as a paid investment consultant for Gerson Lehrman Group. Dr. Choi has served on the advisory boards (less than $10,000 each) for Takeda, URL, and Savient. Dr. Singh has received consultant fees, speaking fees, and/or honoraria (less than $10,000 each) from Ardea, Savient, Allergan, and Novartis, and (more than $10,000) from Takeda, and has received investigator-initiated grants from Takeda and Savient. Dr. Dalbeth has received consultant fees, speaking fees, and/or honoraria (less than $10,000 each) from Takeda, Ardea, and Novartis, has received research funding from Fonterra, and holds a patent from Fonterra for milk products for gout. Dr. Niyyar has received honoraria (less than $10,000) from the American Society of Nephrology. Dr. Kerr has served as a study investigator (more than $10,000 each) for Savient and Nuon. Dr. Edwards has received consultant fees, speaking fees, and/or honoraria (less than $10,000 each) from Savient, Takeda, Ardea, and Regeneron, and (more than $10,000) from Novartis, and has given expert testimony for Novartis. Dr. Mandell has received consultant fees, speaking fees, and/or honoraria (less than $10,000 each) from Savient, Novartis, and Pfizer. Dr. Schumacher has received consultant fees (less than $10,000 each) from Pfizer, Regeneron, West-Ward, and Ardea, and (more than $10,000) from Novartis. Dr. Terkeltaub has received consultant fees (less than $10,000 each) from Takeda, Savient, Ardea, BioCryst, URL, Regeneron, Pfizer, Metabolex, Nuon, Chugai, EnzymeRx, Ajanta, Anadys, Celgene, Isis, and Prescription Solutions, and (more than $10,000) from Novartis, has received grant support from the VA San Diego Healthcare System and the NIH, and has served as a paid investment consultant for Leerink Swann, Medacorp, and Guidepoint.

Submitted for publication January 9, 2012; accepted in revised form June 15, 2012.

health-related quality of life are now better appreciated in many gout patients, particularly those with multiple comorbidities and/or chronic gouty arthritis (13,14). Despite advanced understanding of the molecular bases of hyperuricemia and gouty inflammation and the extensive practice experience of many providers, substantial quality of care gaps exist in gout management (15). Moreover, significant shortfalls in patient education and adherence have been identified in gout (16).

On behalf of the American College of Rheumatology (ACR), we were charged with developing systematic nonpharmacologic and pharmacologic recommendations for effective treatments in gout with an acceptable risk/benefit ratio. Our assignment was to focus on 4 specific domains in gout management. Two of these domains are addressed herein, i.e., urate-lowering therapy (ULT) and chronic gouty arthritis with tophaceous disease detected on physical examination (designated by the ACR with the terminology "chronic tophaceous gouty arthropathy" [CTGA] and specifically represented in the fundamental case scenarios 7–9 described herein). The remaining 2 domains (analgesic and antiinflammatory management of acute gouty arthritis and pharmacologic antiinflammatory prophylaxis of attacks of gouty arthritis) are addressed in part 2 of the guidelines as a separate article (17).

There are multiple lines of epidemiologic and experimental evidence that hyperuricemia, via the effects of excess soluble urate, may play a role in some human renal, cardiovascular, and metabolic comorbidities also frequently associated with gout (7–10). We did not address pharmacologic management of asymptomatic hyperuricemia due to a paucity of prospective, randomized, controlled human research trials in that area (18).

We were charged by the ACR with developing gout recommendations based on evidence as available, at an international level, for rheumatologists and other health care providers, including other subspecialists, primary care practitioners, nurse practitioners, physician assistants, and allied health professionals. The ACR requested that we apply the established RAND/University of California at Los Angeles (UCLA) Appropriateness Method (19) to generate recommendations, and we engaged a diverse international panel of experts. Creating a novel classification of gout as a disease, new gout diagnostic criteria, or a definition of treatment outcomes was beyond the scope of this work. Instead, we generated multifaceted case scenarios to elucidate decision making based primarily on clinical and laboratory test–based data that can be obtained on a gout patient in an office practice setting.

Guidelines for gout management have been generated in the last decade, at the national or multinational society level and independent of industry sponsorship, by the European League Against Rheumatism (EULAR) (20,21), the Dutch College of General Practitioners (22), the Japanese Society of Gout and Nucleic Acid Metabolism (23), and the British Society for Rheumatology (BSR) (24). Moreover, the National Institute for Health and Clinical Excellence single technology appraisal process has been applied to ULT in gout patients receiving febuxostat (25). New guidelines were requested by the ACR, since the understanding of gout risk factors has been greatly augmented by recent clinical research (12). Moreover, ULT options recently increased via clinical development and drug regulatory agency approval of new pharmacologic agents (febuxostat and the biologic drug pegloticase) (26,27). New imaging approaches for gout that can detect radiographic changes of early disease not visualized by plain radiography (e.g., high-resolution ultrasound, dual-energy computed tomography [CT]) (28,29) are being investigated for impact on gout diagnosis, assessment of disease burden and severity, and choices and effectiveness of management. Developments such as these are considered in the work of this committee, which was built on several key assumptions (Table 1).

Table 1. Key assumptions in the process applied to develop the recommendations

1. Recommendations were developed using the RAND/University of California at Los Angeles methodology, which assesses level of evidence and safety and quality, but does not take comparisons of cost and cost-effectiveness of therapies into consideration.
2. The guidelines focused on clinically-based decision making in common scenarios and not on rare case presentations.
3. Multiple scenarios were developed for acute treatment and chronic gout for voting purposes and are NOT meant to be disease classification criteria for gout.
4. The project did not list specific drug choices, contraindications, and dosing in the presence of comorbidities associated with gout or with potential drug–drug interaction. These decisions are left with the practitioner, based on evaluation of the risk/benefit ratio when prescribing each therapy, the drug dosing and safety labeling, and other widely available databases and accessible sources of general medical information about potential drug-related adverse events.
5. When a particular drug is not recommended, it does not imply that it is contraindicated. Similarly, if a hierarchy or sequence of a treatment is recommended, it does not necessarily imply that an agent lower in the hierarchy is contraindicated.
6. It is assumed that the diagnosis of gout was correct before initiation of any management option.
7. It is not always possible for the task force panel to reach a consensus on a case scenario (see Supplemental Figure 3 for examples of voting scenarios, available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658).

The ACR gout guidelines are designed to emphasize safety and quality of therapy and to reflect best practice, as evaluated by a diverse group of experts that examined the level of evidence available at the time. Importantly, societal cost of health care and cost and cost-effectiveness differences between therapies are excluded from analysis by the RAND/UCLA Appropriateness Method (19) (Table 1). Individual results of this work are designated as "recommendations" rather than guidelines, in order to reflect the nonprescriptive nature of decision making evaluated by experts and based on available evidence at the time. The recommendations cannot substitute for individual-

ized direct assessment of the patient, coupled with clinical decision making by a competent health care practitioner. Treatment recommendations also assume appropriate attention to potential drug interactions (e.g., with anticoagulants, azathioprine, amoxicillin) and effects of comorbidities such as diabetes mellitus and renal, cardiac, gastrointestinal, and hepatic disease (Table 1). The motivation, financial circumstances, and preferences of the gout patient play a very important role. Moreover, the recommendations for gout management presented here are not intended to limit or deny third party payor coverage of health care costs for groups or individual patients with gout.

Materials and methods

Project design, development of recommendations, and grading of evidence. The overall design of the project is schematized in Supplemental Figure 1 (available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658). The RAND/UCLA consensus methodology, developed in the 1980s, incorporates both Delphi and nominal group methods (19,30), and was successfully used to develop other guidelines commissioned by the ACR. The purpose of this methodology is to reach a consensus among experts, with an understanding that published literature may not be adequate to provide sufficient evidence for day-to-day clinical decision making. The RAND/UCLA method requires 2 groups of experts: a core expert panel (CEP) that provides input into case scenario development and preparation of a scientific evidence report, and a task force panel (TFP) that votes on these case scenarios. Our CEP consisted of leaders for each domain (see Supplemental Figure 2, available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658). Pharmacologic approaches and diet, lifestyle, and nonpharmacologic measures (e.g., weight loss, exercise) were addressed within each domain. The CEP leaders communicated with an international panel of gout experts and the principal investigators (PIs; JDF, PPK, DK, RT) to develop initial case scenarios that reflect broad differences in severity of the disease and its clinical manifestations. In addition, there were weekly interactive teleconferences between the domain leaders and PIs to refine case scenarios. Although a previous systematic review for gout has been performed by EULAR, as a prime example, we performed our own systematic review of pertinent literature. The resultant scientific evidence report was given to the TFP in conjunction with clinical scenarios representing differing degrees of disease activity. There were multiple questions of interest and alternative options presented for each case scenario.

By ACR mandate, the TFP had a majority of members without a perceived potential conflict of interest (COI), and had diverse experience and expertise, as described in detail in Supplemental Figure 2 (available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658). The TFP included 7 rheumatologists (including 1 Chair of Internal Medicine and 1 Internal Medicine Residency Training Program Director), 2 primary care physicians, a nephrologist, and a patient representative. There were 2 rounds of ratings, the first anonymous, with the members of the TFP instructed to rank each of the potential elements of the guidelines on a risk/benefit basis ranging from 1–9 on a Likert scale using the Delphi process, followed by a face-to-face group discussion and then revoting of the same scenarios. A vote of 1–3 on the Likert scale was rated as *inappropriate* (risks clearly outweigh the benefits), a vote of 4–6 was considered *uncertain* (risk/benefit ratio is uncertain), and a vote of 7–9 was rated as *appropriate* (benefits clearly outweigh the risks). Samples of votes taken and results are provided in Supplemental Figure 3 (available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658). Votes on case scenarios were translated into recommendations if the median voting score was graded 7–9 (appropriate) and if there was no significant disagreement, defined as no more than 1 of 3 of the votes graded as inappropriate for the scenario. The final rating was done anonymously in a 2-day face-to-face meeting, facilitated by an experienced moderator (NW). During the face-to-face TFP meeting, some case scenarios were clarified for content or verbiage and revoted on by the TFP.

The level of evidence supporting each recommendation was ranked based on previous methods used by the American College of Cardiology (31) and applied to recent ACR recommendations (32,33). Level A grading was assigned to recommendations supported by multiple (i.e., >1) randomized clinical trials or meta-analyses. Level B grading was assigned to the recommendations derived from a single randomized trial or nonrandomized studies. Level C grading was assigned to consensus opinion of experts, case studies, or standard of care.

Systematic review. PubMed and the Cochrane Central Register of Controlled Trials from the 1950s to the present were searched to find articles on gout with the help of an experienced librarian. We used a search strategy based on the Cochrane Highly Sensitive Search Strategy for identifying randomized trials. The search was expanded to include articles discussing research designs such as cohort, case–control, and cross-sectional studies. Limits included English language and the exclusion of "animal only" studies. The exact terms, process, and results of the search are summarized in Supplemental Figure 4 (available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658).

Clinical case descriptions. The TFP evaluated clinical scenarios with differences in frequency of acute gout symptoms and differences related to the presence or extent of chronic findings (tophi, synovitis) on physical examination, similar to what a clinician might see in a busy practice. Scenarios were divided into mild, moderate, and severe disease activity in each of 3 distinct "treatment groups" (Figures 1A and B). In generating these 9 fundamental clinical case scenarios, mild disease activity levels in each treatment group were meant to represent patients at the lowest disease activity level for which most clinicians would consider initiating or altering a specific med-

GOUT CASE SCENARIOS

Symptoms	Tophus or Tophi detected on Physical Exam	Frequency	CASE SCENARIO NUMBER
Intermittent symptoms	NO	Infrequent Symptoms (≤ 1 attack/yr)	*1*
	NO	Frequent Symptoms (2-6 attacks/yr)	*2*
	NO	Very Frequent Symptoms (> 7 attacks/yr)	*3*
Intermittent symptoms	YES	Infrequent Symptoms (≤ 1 attack/yr)	*4*
	YES	Frequent Symptoms (2-6 attacks/yr)	*5*
	YES	Very Frequent Symptoms (> 7 attacks/yr)	*6*

A

Case scenarios for Chronic Tophaceous Gouty Arthropathy

Disease Severity	Characteristics	CASE SCENARIO NUMBER
Mild	•Simple chronic tophaceous gouty arthropathy •Affecting 1 joint •Stable disease	*7*
Moderate	•Simple chronic tophaceous gouty arthropathy •Affecting 2-4 joints •Stable disease	*8*
Severe	•Chronic tophaceous gouty arthropathy of >4 joints OR • ≥1 unstable, complicated, severe articular tophus or tophi	*9*

B

Figure 1. Fundamental case scenarios evaluated by the task force panel (TFP). The TFP evaluated a broad spectrum of severity of gout, with presenting clinical information comparable to that encountered in practice. Scenarios were formulated iteratively by the core expert panel, as described in the text, and were not intended to serve as disease classification criteria. All case scenarios assumed that the diagnosis of gout was correct, and that there was some evidence of gout disease activity. Three distinct "treatment groups" for these recommendations, each with 3 case scenarios designed to succinctly represent clinically-based decision making and totaling 9 in all, are shown. The treatment group with intermittent attacks of acute gout but no tophi detected on physical examination was subdivided based on increasing yearly frequency of episodes of acute gouty arthritis of at least moderate to severe pain intensity (case scenarios 1–3; **A**). Gout associated with clinically apparent high body urate burden was evaluated in case scenarios where there were ≥1 tophi on physical examination, and either **A,** intermittently symptomatic acute gouty arthritis (case scenarios 4–6), or **B**, chronic joint symptoms due to synovitis attributable to gout or articular tophus or tophi in case scenarios 7–9 (the domain termed chronic tophaceous gouty arthropathy [CTGA]). Severity of case scenarios in the CTGA domain was distinguished by extent and characteristics of the tophi and chronic arthropathy, with variable inflammatory and deforming features detected on physical examination (see Figure 2).

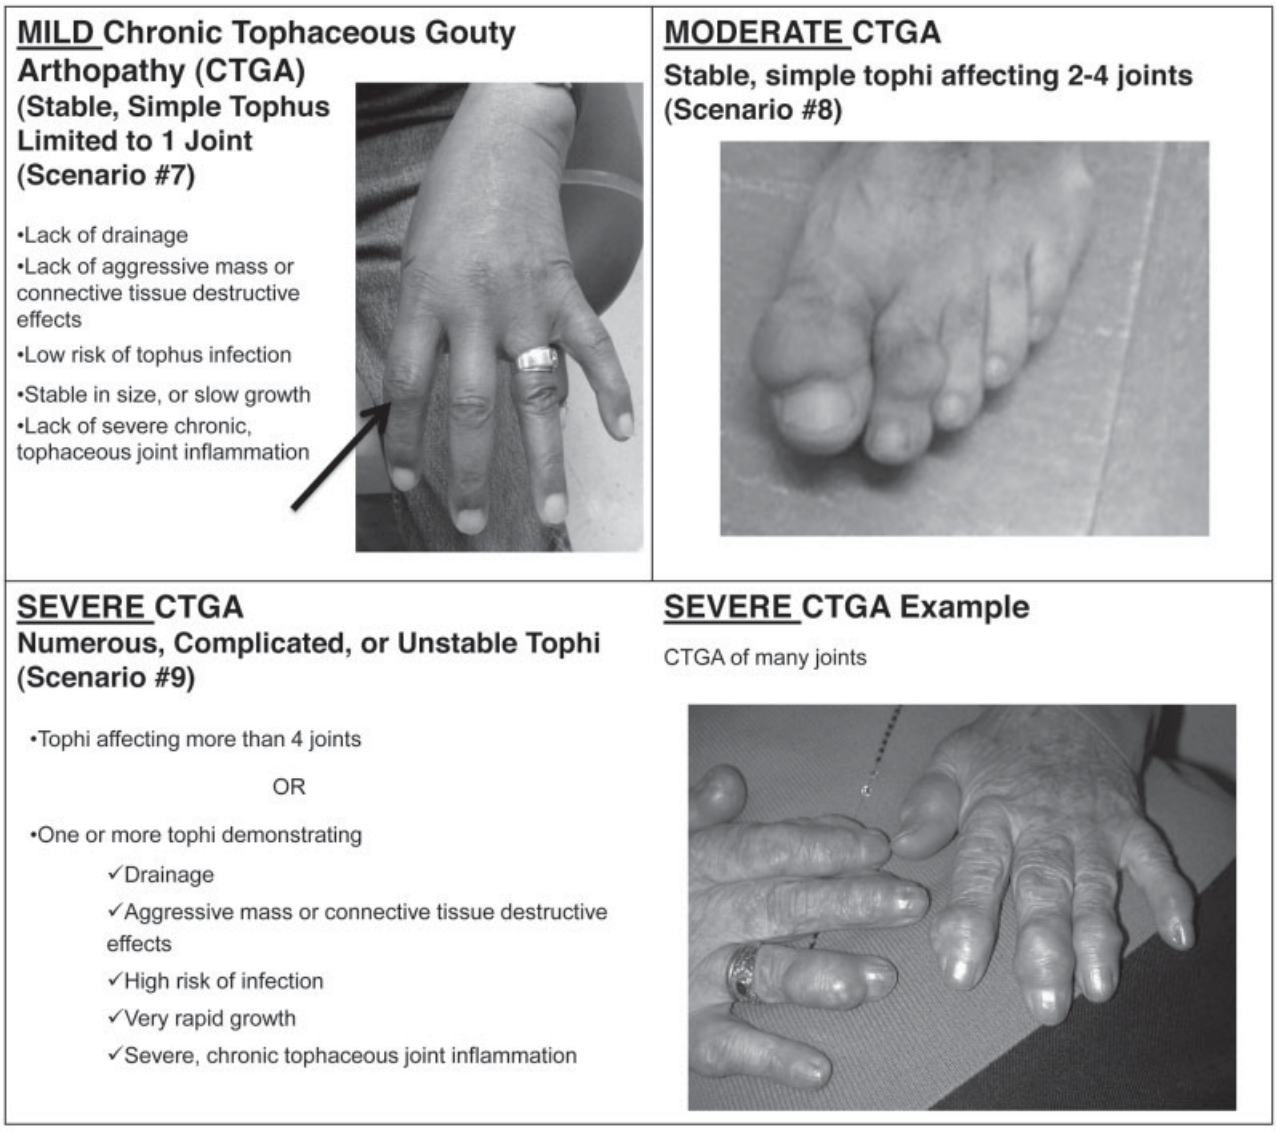
ication regimen. Conversely, the severe disease activity level was intended to represent patients with disease activity greater than or equal to that of the "average" subject studied in a clinical trial. The case scenarios were not intended to serve as classification criteria. To allow the TFP to focus on management decisions, each case scenario had the assumption that the diagnosis of gout was correct. In addition, it was assumed that there was some clinical evidence of gout disease activity. This included intermittent symptoms of variable frequency, specifically presented to the TFP as episodes of acute gouty arthritis of at least moderate to severe pain intensity (17). Other clinical evidence of gout disease activity, presented to the TFP in specific case scenarios, was tophi detected by physical examination, or alternatively, chronic symptomatic arthritis (i.e., "chronic arthropathy" or "synovitis") due to gout, with or without confirmed joint damage (e.g., deformity, erosion due to gout on an imaging study) (Figure 2). Hyperuricemia was defined here as a serum urate level >6.8 mg/dl (2). We determined all aspects of case scenario definitions by a structured iterative process, using regular e-mail and teleconferences at least once per month. Multiple revisions to the proposed parameters were carried out, until accepted by the CEP domain leaders.

Definitions of pharmacologic therapeutic agents. Medication classes evaluated in the case scenarios were defined as follows: xanthine oxidase inhibitor (XOI) refers to allopurinol or febuxostat, and uricosuric agents were defined to include agents available in the US (probenecid and off-label use [as uricosuric therapy] of fenofibrate and losartan), but did not include sulfinpyrazone or benzbromarone. Other agents and modalities were self-explanatory. Evaluation by the TFP of effectiveness of a given therapeutic option assumed that patients in the case scenarios received the maximum tolerated typical dose for a period of time sufficient to accurately assess therapeutic response, unless otherwise indicated.

Managing perceived potential COI. Perceived potential COI was managed in a prospective and structured manner. Specifically, all participants intellectually involved in the project, whether authors or not, were required to fully and prospectively disclose relationships with pharmaceutical companies with a material interest in gout (see Supplemental Figure 2 and Appendix A, available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658). Disclosures were updated every 6 months, and for the PIs, CEP, and TFP, updated just prior to the face-to-face meeting. A summary listing of all perceived potential COI was disseminated to all participants in the project, and is available in Supplemental Appendix A (available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658). Based on the policies of the ACR, which are aligned with those of many medical societies, no more than 49% of the project participants could have a COI at any given time. It was required that the project PI (JDF) remain without perceived potential COI prior to and during the process.

Results

Primary principles of management for all gout case scenarios. The TFP generated recommendations for a systematic nonpharmacologic and pharmacologic management approach intended to be applicable to all patients with gout, which is summarized in Figure 3. This was based on the assumption that the diagnosis of gout was correct before initiation of management. The approach highlighted patient education on the disease and treat-



MILD Chronic Tophaceous Gouty Arthopathy (CTGA)
(Stable, Simple Tophus Limited to 1 Joint
(Scenario #7)
•Lack of drainage

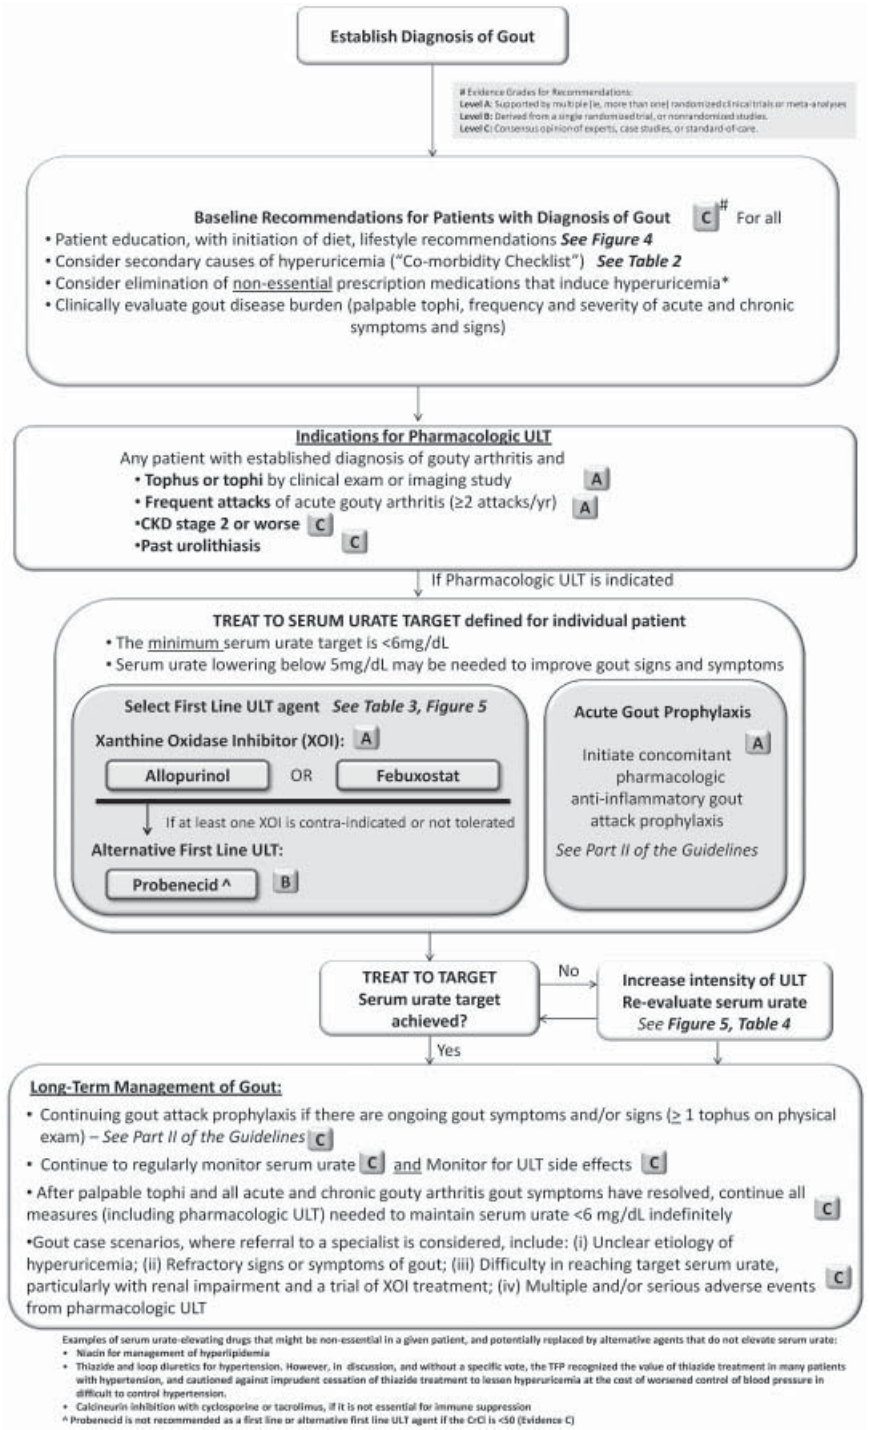
Figure 2. Detailed pictorial representations of chronic arthropathy in chronic tophaceous gouty arthropathy (CTGA) case scenarios presented to the task force panel (TFP). A core element of our approach was to present the TFP and the readership with specifically detailed summaries of the CTGA case scenarios (case scenarios 7–9 in Figure 1B), including pictorial examples, to allow focus on clinical information that prompts management decisions. The photograph on the top left was provided by Dr. Robert Terkeltaub; the photographs on the top and bottom right were provided by Dr. Fernando Perez-Ruiz.

ments and their objectives, and initiation of diet and lifestyle recommendations, including the particular role of uric acid excess in gout and as the key long-term treatment target (evidence B) (34). The TFP also recommended, on a case-by-case basis, careful consideration of potential elimination of serum urate–elevating prescription medications that might be nonessential for the optimal management of comorbidities (e.g., hypertension, hyperlipidemia, or major organ transplant) in a given patient. Prime examples of urate-elevating medications are thiazide and loop diuretics, niacin, and calcineurin inhibitors (evidence C). However, the TFP, without a specific vote, recognized the particular benefits of thiazides for blood pressure control and outcomes in many patients with hypertension. Although low-dose acetylsalicylic acid (aspirin ≤325 mg daily) elevates serum urate, the TFP did not recommend discontinuation of this modality as cardiovascular disease prophylaxis in gout patients. In discussion, without a specific vote, the TFP viewed the relative risks specifically attributable to the modest effects of low-dose aspirin on serum urate as negligible in gout management.

The TFP recommended that clinicians consider causes of hyperuricemia for all gout patients, and recommended a specific comorbidity checklist (evidence C) (Table 2). In doing so, the TFP specially recommended consideration, and if indicated, medical evaluation of certain agents and disorders that cause uric acid underexcretion or overproduction, which thereby could merit laboratory investigations such as urinalysis, renal ultrasound, a complete blood cell count with differential cell count, or urine uric acid quantification, as indicated. In this context, the TFP specifically recommended screening for uric acid overpro-



Establish Diagnosis of Gout
Evidence Grades for Recommendations:
Level A: Supported by multiple (ie, more than one) randomized clinical trials or meta-analyses
Level B: Derived from a single randomized trial, or nonrandomized studies.
Level C: Consensus opinion of experts, case studies, or standard-of-care.
Baseline Recommendations for Patients with Diagnosis of Gout C# For all
• Patient education, with initiation of diet, lifestyle recommendations See Figure 4
• Consider secondary causes of hyperuricemia ("Co-morbidity Checklist") See Table 2
• Consider elimination of non-essential prescription medications that induce hyperuricemia*
• Clinically evaluate gout disease burden (palpable tophi, frequency and severity of acute and chronic symptoms and signs)
Indications for Pharmacologic ULT
Any patient with established diagnosis of gouty arthritis and
• Tophus or tophi by clinical exam or imaging study A
• Frequent attacks of acute gouty arthritis (≥2 attacks/yr) A
•CKD stage 2 or worse C
•Past urolithiasis C
If Pharmacologic ULT is indicated
TREAT TO SERUM URATE TARGET defined for individual patient
• The minimum serum urate target is <6mg/dL
• Serum urate lowering below 5mg/dL may be needed to improve gout signs and symptoms
Select First Line ULT agent See Table 3, Figure 5
Xanthine Oxidase Inhibitor (XOI): A
Allopurinol OR Febuxostat
If at least one XOI is contra-indicated or not tolerated
Alternative First Line ULT:
Probenecid ^ B
Acute Gout Prophylaxis
A
Initiate concomitant pharmacologic anti-inflammatory gout attack prophylaxis
See Part II of the Guidelines
TREAT TO TARGET Serum urate target achieved?
No
Increase intensity of ULT Re-evaluate serum urate See Figure 5, Table 4
Yes
Long-Term Management of Gout:
• Continuing gout attack prophylaxis if there are ongoing gout symptoms and/or signs (≥ 1 tophus on physical exam) – See Part II of the Guidelines C
• Continue to regularly monitor serum urate C and Monitor for ULT side effects C
• After palpable tophi and all acute and chronic gouty arthritis gout symptoms have resolved, continue all measures (including pharmacologic ULT) needed to maintain serum urate <6 mg/dL indefinitely C
•Gout case scenarios, where referral to a specialist is considered, include: (i) Unclear etiology of hyperuricemia; (ii) Refractory signs or symptoms of gout; (iii) Difficulty in reaching target serum urate, particularly with renal impairment and a trial of XOI treatment; (iv) Multiple and/or serious adverse events from pharmacologic ULT C
Examples of serum urate-elevating drugs that might be non-essential in a given patient, and potentially replaced by alternative agents that do not elevate serum urate:
• Niacin for management of hyperlipidemia
• Thiazide and loop diuretics for hypertension. However, in discussion, and without a specific vote, the TFP recognized the value of thiazide treatment in many patients with hypertension, and cautioned against imprudent cessation of thiazide treatment to lessen hyperuricemia at the cost of worsened control of blood pressure in difficult to control hypertension.
• Calcineurin inhibition with cyclosporine or tacrolimus, if it is not essential for immune suppression
^ Probenecid is not recommended as a first line or alternative first line ULT agent if the CrCl is <50 (Evidence C)

Figure 3. Baseline recommendations and overall strategic plan for patients with gout. This algorithm summarizes overall treatment strategies and flow of management decisions for gout. Certain elements, including nonpharmacologic and pharmacologic measures, the approach to refractory disease, and treatment and antiinflammatory prophylaxis of acute gout attacks, are developed further in Tables 2–4 and Figures 4 and 5, and in part 2 of the guidelines, as referenced in the figure. Evidence grades (A–C, as indicated) are summarized for each task force panel (TFP) recommendation, and the text discusses in detail each aspect of clinical decision making. ULT = urate-lowering therapy; CKD = chronic kidney disease; CrCl = creatinine clearance.

Table 2. Specific recommendation of a comorbidity checklist for gout patients

Appropriate to consider in the clinical evaluation, and if clinically indicated, to evaluate (evidence C for all)*
Obesity, dietary factors
Excessive alcohol intake
Metabolic syndrome, type 2 diabetes mellitus
Hypertension†
Hyperlipidemia, modifiable risk factors for coronary artery disease or stroke
Serum urate–elevating medications†
History of urolithiasis
Chronic kidney, glomerular, or interstitial renal disease (e.g., analgesic nephropathy, polycystic kidney disease)
In selected cases, potential genetic or acquired cause of uric acid overproduction (e.g., inborn error of purine metabolism or psoriasis, myeloproliferative, or lymphoproliferative disease, respectively)
Lead intoxication

* Evidence grades for recommendations: level A = supported by multiple (i.e., >1) randomized clinical trials or meta-analyses; level B = derived from a single randomized trial or nonrandomized studies; level C = consensus opinion of experts, case studies, or standard of care.
† The task force panel, without a specific vote, recognized the particular benefits of thiazide diuretics for blood pressure control and outcomes in many patients with hypertension.

duction (by urine uric acid evaluation) in patient subsets with gout clinical disease onset before age 25 years (evidence C) or a history of urolithiasis (evidence C).

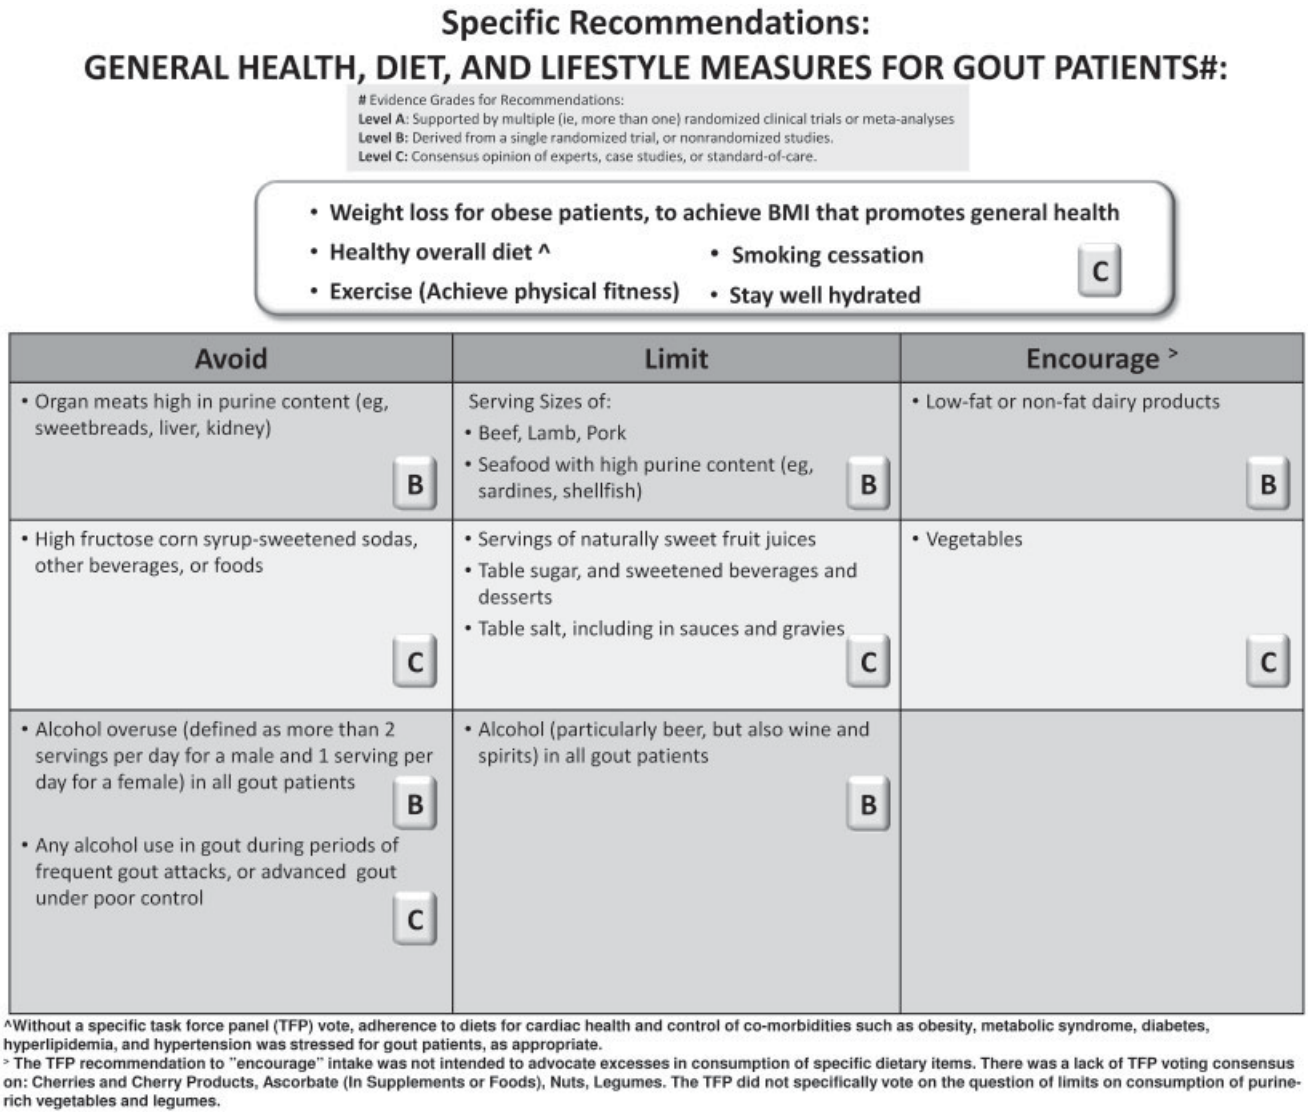
The TFP provided guidance for referral to a specialist, with caution to avoid appearing self-serving. Although limited by the absence of outcomes data on potential benefits of referral, the TFP recommended that gout case scenarios including any of the following should be among those where referral to a specialist is considered (evidence C for all): 1) unclear etiology of hyperuricemia; 2) refractory signs or symptoms of gout; 3) difficulty in reaching the target serum urate level, particularly with renal impairment and a trial of XOI treatment; and 4) multiple and/or serious adverse events from pharmacologic ULT.

Clinical evaluation of gout disease activity and burden. The TFP recommended clinical evaluation of gout disease symptom severity and burden in individual patients by history and a thorough physical examination for symptoms of arthritis and signs such as tophi and acute and chronic synovitis (evidence C). To be actionable by clinicians, the authors without a specific TFP vote suggested that clinicians can work with patients to record and estimate the number per year and severity (17) of acute attacks of gouty arthritis per year.

Core recommendations for nonpharmacologic ULT measures in gout. The TFP recommended certain diet and lifestyle measures for the majority of patients with gout (evidence B and C for individual measures) (Figure 4). Many of the diet and lifestyle measures were recommended for decreasing the risk and frequency of acute gout attacks (12) and lowering serum urate levels, but the primary emphasis of the TFP recommendations in Figure 4 was on diet and lifestyle choices for promotion and maintenance of ideal health and prevention and optimal management of life-threatening comorbidities in gout patients, including coronary artery disease (35,36) and obesity, metabolic syndrome, diabetes mellitus, hyperlipidemia, and hypertension.

Dietary recommendations were grouped into 3 simple qualitative categories, termed "avoid," "limit," or "encourage" (Figure 4). This approach, with rare exceptions (37,38), reflected a general lack of specific evidence from prospective, blinded, randomized clinical intervention trials that linked consumed quantities of individual dietary components to changes in either serum urate levels or gout outcomes. Notably, the replication of hazardous lifestyle risk factors in a conventional clinical research trial would potentially pose both design and ethical difficulties. As such, the TFP deliberated on evidence regarding the impact of exposures to alcohol or purine-rich foods in a short timeframe. The evidence sources were epidemiologic studies of hyperuricemia and incident gout, including long-term prospective analyses (39–42) and internet-based case-crossover studies of specific exposures (43,44). The TFP recommended that gout patients limit their consumption of purine-rich meat and seafood (evidence B) (44) as well as high fructose corn syrup–sweetened soft drinks and energy drinks (evidence C), and encouraged the consumption of low-fat or nonfat dairy products (evidence B) (43) (Figure 4). The TFP voted to encourage vegetable intake in gout patients (evidence C) (Figure 4), having considered evidence in healthy subjects for lowered serum urate levels and urine urolithiasis risk factors associated with dietary vegetable intake (43,45). However, there was no specific TFP vote on the question of avoidance of excess purine intake from food sources other than meat and seafood, such as vegetables and legumes, in gout patients (44). The TFP recommended reduced consumption of alcohol (particularly beer, but also wine and spirits) and avoidance of alcohol overuse in all gout patients (evidence B) (Figure 4). The TFP further recommended abstinence from alcohol consumption for gout patients during periods of active arthritis, especially with inadequate medical control of the disorder and in CTGA (evidence C) (46). Significantly, in discussion by the TFP, without a specific vote, the TFP recognized that diet and lifestyle measures alone provide therapeutically insufficient serum urate–lowering effects and/or gout attack prophylaxis for a large fraction of individuals with gout (12). For example, some clinical trials on diet and fitness have reported only an ~10–18% decrease in serum urate (43). In further discussion by the TFP, again without a specific vote, the TFP viewed this degree of serum urate level lowering as beneficial for all case scenarios, but insufficient to achieve an effective serum urate target in those with sustained hyperuricemia substantially above 7 mg/dl.

Core recommendations for pharmacologic ULT, including the serum urate target. Here, and with all other recommendations for drug therapy in parts 1 and 2 of the 2012 ACR guidelines for gout, the recommendations assumed a lack of contraindications, intolerance, serious adverse events, or drug–drug interactions for given agents.



Specific Recommendations:
GENERAL HEALTH, DIET, AND LIFESTYLE MEASURES FOR GOUT PATIENTS#:
Evidence Grades for Recommendations:
Level A: Supported by multiple (ie, more than one) randomized clinical trials or meta-analyses
Level B: Derived from a single randomized trial, or nonrandomized studies.
Level C: Consensus opinion of experts, case studies, or standard-of-care.
• Weight loss for obese patients, to achieve BMI that promotes general health
• Healthy overall diet ^
• Exercise (Achieve physical fitness)
• Smoking cessation
• Stay well hydrated
C
Avoid
Limit
Encourage >
• Organ meats high in purine content (eg, sweetbreads, liver, kidney)
B
Serving Sizes of:
• Beef, Lamb, Pork
• Seafood with high purine content (eg, sardines, shellfish)
B
• Low-fat or non-fat dairy products
B
• High fructose corn syrup-sweetened sodas, other beverages, or foods
C
• Servings of naturally sweet fruit juices
• Table sugar, and sweetened beverages and desserts
• Table salt, including in sauces and gravies
C
• Vegetables
C
• Alcohol overuse (defined as more than 2 servings per day for a male and 1 serving per day for a female) in all gout patients
B
• Any alcohol use in gout during periods of frequent gout attacks, or advanced gout under poor control
C
• Alcohol (particularly beer, but also wine and spirits) in all gout patients
B
^Without a specific task force panel (TFP) vote, adherence to diets for cardiac health and control of co-morbidities such as obesity, metabolic syndrome, diabetes, hyperlipidemia, and hypertension was stressed for gout patients, as appropriate.
> The TFP recommendation to "encourage" intake was not intended to advocate excesses in consumption of specific dietary items. There was a lack of TFP voting consensus on: Cherries and Cherry Products, Ascorbate (In Supplements or Foods), Nuts, Legumes. The TFP did not specifically vote on the question of limits on consumption of purine-rich vegetables and legumes.

Figure 4. Specific task force panel (TFP) recommendations on general health, diet, and lifestyle measures for gout patients. The TFP recommendations on nonpharmacologic measures for gout patients are shown, including a program of broad diet and lifestyle measures. The recommendations encompass measures not only for decreasing the risk and frequency of acute gout attacks and lowering serum urate, but also with a major emphasis on maintenance of ideal health and prevention and best practice management of cardiovascular and metabolic diseases. Dietary recommendations were grouped into 3 simple qualitative categories, termed "avoid," "limit," and "encourage," reflecting a general lack of specific evidence from prospective, blinded, randomized clinical intervention trials linking consumed quantities of individual dietary components to changes in either serum urate or to gout signs and symptoms. Specific TFP votes on dietary components resulting in a "lack of consensus" are also cited. BMI = body mass index.

The TFP recommended gout with CKD stage 2–5 or end-stage renal disease as an appropriate indication, by itself, for pharmacologic ULT (evidence C) in patients with prior gout attacks and current hyperuricemia. In pharmacologic ULT, certain treatment choices (e.g., probenecid) and drug dosing decisions (e.g., allopurinol) are impacted by the creatinine clearance. The TFP, without a direct vote, discussed and recognized the clinical value of accurate measurement of creatinine clearance, not simply the serum creatinine, in ascertaining the degree of renal impairment. However, the scope of the project did allow for detailed prescriptive recommendations regarding specific ULT drug doses, usage of individual agents in the presence of a given degree of either renal impairment, or other comorbidities such as hepatic impairment.

TFP recommendations for pharmacologic ULT, shown graphically in Figure 3, included recommendation of XOI therapy with either allopurinol or febuxostat as the first-line pharmacologic approach (evidence A). The panel did not preferentially recommend either XOI over the other XOI drug. In doing so, the TFP weighed the lack of published safety data for febuxostat in the setting of stage 4 or worse CKD. Probenecid was recommended as an alternative first-line pharmacologic ULT option in the setting of contraindication or intolerance to at least 1 XOI agent (evidence B). However, the TFP did not recommend probenecid as a first-line ULT monotherapy in those with a creatinine clearance below 50 ml/minute.

The TFP recommended that pharmacologic ULT could be started during an acute gout attack, provided that effec-

tive antiinflammatory management has been instituted (evidence C). The TFP recommended regular monitoring of serum urate (every 2–5 weeks) during ULT titration, including continuing measurements once the serum urate target is achieved (every 6 months; evidence C). The TFP weighed this measure as particularly useful to monitor adherence, given that poor adherence to ULT is a common problem in gout patients (16).

The TFP recommended that the goal of ULT is to achieve a serum urate level target at a minimum of <6 mg/dl in all gout case scenarios (evidence A). Moreover, the TFP recommended that the target serum urate level should be lowered sufficiently to durably improve signs and symptoms of gout, including palpable and visible tophi detected by physical examination, and that this may involve therapeutic serum urate level lowering to below 5 mg/dl (evidence B).

Recommendations specific to allopurinol dosing and pharmacogenetics. TFP recommendations for use of allopurinol in gout are summarized in Table 3. Importantly, the TFP recommended that the starting dosage of allopurinol should be no greater than 100 mg per day (evidence B) (47), consistent with prior Food and Drug Administration (FDA) and EULAR guidelines (21). The rationale of the TFP was partly that a low allopurinol starting dose could reduce early gout flares after ULT initiation (26), and partly as a component of risk management with respect to the potential for severe hypersensitivity reaction to allopurinol (47), discussed in further detail below. The TFP recommended gradual upward titration of the allopurinol maintenance dose every 2–5 weeks to an appropriate maximum dose for gout, in order to treat to the serum urate target appropriate for the individual patient (evidence C).

The TFP weighed robust evidence that allopurinol monotherapy at doses of 300 mg or less daily failed to achieve the serum urate level target of <6 mg/dl (26,46) or <5 mg/dl (48,49) in more than half of the subjects with gout. The TFP reviewed small studies in which the allopurinol dose was titrated above 300 mg daily in gout with overall success in achieving the serum urate target (49,50). Importantly, in doing so, the TFP also recommended that the maintenance dosage of allopurinol can be raised above 300 mg per day, even in those with renal impairment, provided there is adequate patient education and regular monitoring for drug hypersensitivity and other adverse events, such as pruritis, rash, and elevated hepatic transaminases, as well as attention to potential development of eosinophilia (evidence B).

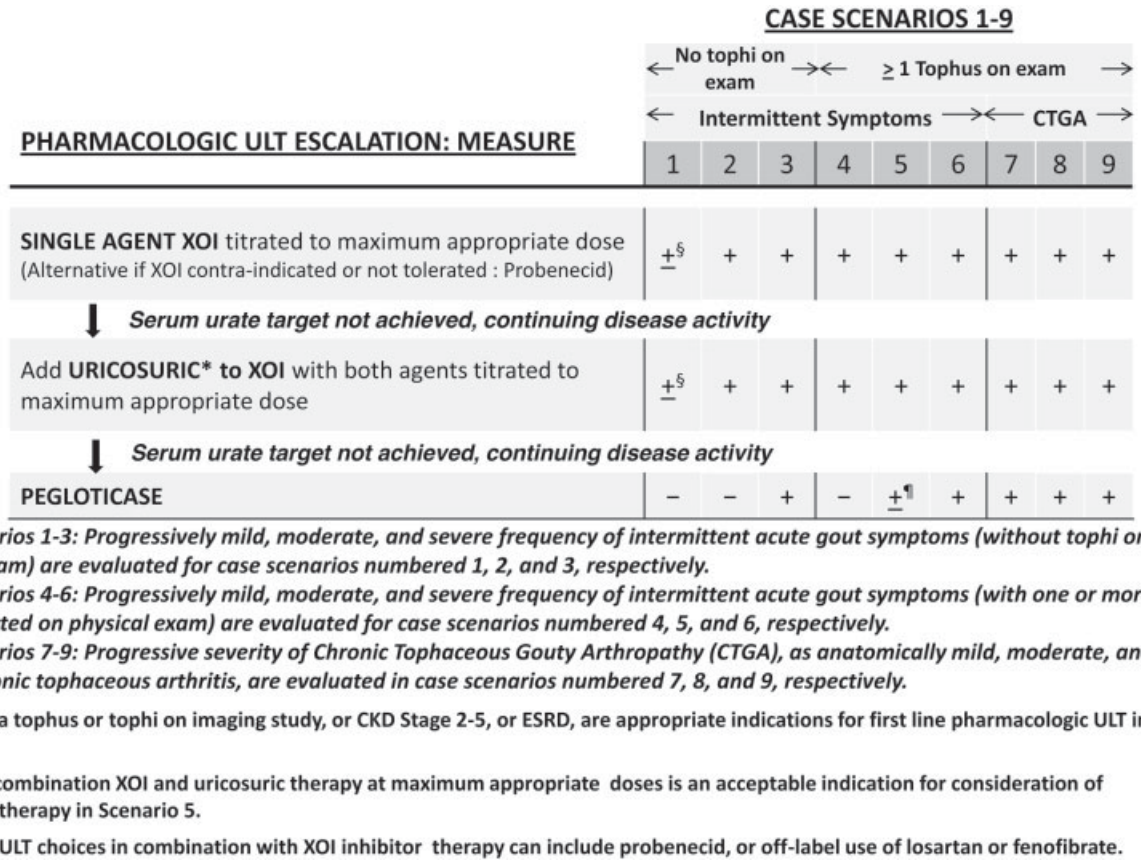
The TFP next considered the issue of measures to reduce the incidence of severe allopurinol hypersensitivity reactions, here termed allopurinol hypersensitivity syndrome (AHS). TFP discussion recognized the potential for hospitalization and severe morbidity and the reported mortality rate of 20–25% in AHS (51,52). The estimated incidence of AHS is ~1:1,000 in the US, and its spectrum includes not only Stevens-Johnson syndrome and toxic epidermal necrolysis, but also systemic disease with a clinical constellation of features such as eosinophilia, vasculitis, rash, and major end-organ disease (53). Concurrent thiazide use and renal impairment have been implicated as risk factors for AHS (50,54,55). A widely employed risk management strategy has been a non–evidence-based algorithm for allopurinol maintenance dosing, calibrated to renal impairment (evidence C) (56); importantly, the TFP did not recommend this strategy.

In their evaluation of the allopurinol starting dose as a component of risk management strategy, the TFP first weighed evidence that the highest risk of severe allopurinol hypersensitivity reaction is in the first few months of therapy. A recent case–controlled retrospective analysis of AHS and allopurinol starting dose (47) further supported the aforementioned recommendation by the TFP of a starting dose of allopurinol of no more than 100 mg daily, and the TFP recommendation of an even lower starting dose of allopurinol (50 mg daily) in stage 4 or worse CKD (evidence B).

Table 3. Core recommendations in the use of allopurinol and uricosuric ULT in gout*

Allopurinol
Starting dosage should be no greater than 100 mg/day for any patient, and start at 50 mg/day in stage 4 or worse CKD (evidence B)
Gradually titrate maintenance dose upward every 2–5 weeks to appropriate maximum dose in order to treat to chosen SUA target (evidence C)
Dose can be raised above 300 mg daily, even with renal impairment, as long as it is accompanied by adequate patient education and monitoring for drug toxicity (e.g., pruritis, rash, elevated hepatic transaminases; evidence B)
Prior to initiation, consider HLA–B*5801 in selected patients, specifically in subpopulations at higher risk for severe allopurinol hypersensitivity reaction (e.g., Koreans with stage 3 or worse CKD, and Han Chinese and Thai irrespective of renal function; evidence A)
Uricosuric therapy
Probenecid is the first choice among uricosuric agents for ULT monotherapy (evidence B)
In gout patients with a creatinine clearance <50 ml/minute, probenecid is not recommended as first-line ULT monotherapy (evidence C)
Use of agents other than probenecid with clinically significant uricosuric effects, such as fenofibrate and losartan, can be therapeutically useful as components of a comprehensive ULT strategy (evidence B)
History of urolithiasis contraindicates first-line uricosuric urate-lowering monotherapy (evidence C)
Urinary uric acid should be measured before initiation of uricosuric ULT (evidence C)
Elevated urine uric acid indicative of uric acid overproduction contraindicates uricosuric ULT (evidence C)
Continue to monitor urinary uric acid during uricosuric ULT (evidence C)
Consider urine alkalinization (e.g., with potassium citrate) with monitoring of urine pH, in addition to increased fluid intake, as a risk management strategy for urolithiasis (evidence C)

* ULT = urate-lowering therapy; CKD = chronic kidney disease; SUA = serum uric acid.



CASE SCENARIOS 1-9
No tophi on exam
≥ 1 Tophus on exam
Intermittent Symptoms
CTGA
PHARMACOLOGIC ULT ESCALATION: MEASURE
1 2 3 4 5 6 7 8 9
SINGLE AGENT XOI titrated to maximum appropriate dose
(Alternative if XOI contra-indicated or not tolerated : Probenecid)

Add URICOSURIC* to XOI with both agents titrated to maximum appropriate dose
± § + + + + + + + +
Serum urate target not achieved, continuing disease activity
PEGLOTICASE
– – + – ± ¶ + + + +
Case Scenarios 1-3: Progressively mild, moderate, and severe frequency of intermittent acute gout symptoms (without tophi on physical exam) are evaluated for case scenarios numbered 1, 2, and 3, respectively.
Case Scenarios 4-6: Progressively mild, moderate, and severe frequency of intermittent acute gout symptoms (with one or more tophi detected on physical exam) are evaluated for case scenarios numbered 4, 5, and 6, respectively.
Case Scenarios 7-9: Progressive severity of Chronic Tophaceous Gouty Arthropathy (CTGA), as anatomically mild, moderate, and severe chronic tophaceous arthritis, are evaluated in case scenarios numbered 7, 8, and 9, respectively.
§ Finding of a tophus or tophi on imaging study, or CKD Stage 2-5, or ESRD, are appropriate indications for first line pharmacologic ULT in Scenario 1.
¶ Failure of combination XOI and uricosuric therapy at maximum appropriate doses is an acceptable indication for consideration of Pegloticase therapy in Scenario 5.
*Uricosuric ULT choices in combination with XOI inhibitor therapy can include probenecid, or off-label use of losartan or fenofibrate.

Figure 5. Case scenario–specific escalation of pharmacologic urate-lowering therapy (ULT) in gout, including approach to refractory disease. The figure, which accompanies Table 4, shows task force panel (TFP) recommendations for patients with continuing gout disease activity and focuses on escalating pharmacologic ULT measures, particularly for refractory disease. Each of the fundamental case scenarios is considered. Case scenario numbering of 1–9 refers to those gout clinical scenarios specifically detailed in Figures 1A and B above. The chronic tophaceous gouty arthropathy (CTGA) case scenarios numbered 7–9 are additionally shown in photographs in Figure 2. These recommendations specifically assume that for each case scenario: 1) the serum urate target needed to achieve improved gout signs and symptoms has not yet been achieved, 2) appropriate nonpharmacologic ULT measures have been applied, and 3) appropriate treatment and antiinflammatory prophylaxis are employed for attacks of acute gouty arthritis. Evidence grades for individual TFP votes to recommend that are shown here are summarized in the text. In the figure, the decision-making symbol + indicates therapeutic appropriateness, with − indicative of either a therapeutically inappropriate measure or one with uncertain risk:benefit ratio. The decision-making symbol ± indicates that the TFP recommended this therapeutic measure as appropriate only in specific conditions in a clinical scenario, marked by the symbol § or ¶ that refers to particular circumstances described below the figure. CKD = chronic kidney disease; ESRD = end-stage renal disease; XOI = xanthine oxidase inhibitor.

Table 4. Summary of recommendations for case scenarios of refractory disease in gout (Figure 5), including combination oral ULT and use of pegloticase*

Attempt upward dose titration of 1 XOI to respective maximum appropriate dose (evidence A)
Febuxostat can be substituted for allopurinol or vice versa in the event of drug intolerance and adverse events, and such a substitution should be considered after initial failure of upward dose titration of 1 XOI (evidence C)†
Effective therapeutic options include addition of a uricosuric agent (e.g., probenecid, fenofibrate, or losartan) to an XOI drug (evidence B) or vice versa (evidence C)
Pegloticase is appropriate for patients with severe gout disease burden and refractoriness to, or intolerance of, conventional and appropriately dosed ULT (evidence A)‡
Pegloticase therapy is not recommended as first-line ULT agent for any case scenarios
LACK OF CONSENSUS: appropriate duration of pegloticase therapy relative to intended and achieved decrease in symptoms and signs of gout, including decrease in tophus size

* ULT = urate-lowering therapy; XOI = xanthine oxidase inhibitor.
† Important drug label information includes that febuxostat and allopurinol should not be used in combination with each other.
‡ Important drug label information includes that pharmacologic oral ULT agents should be discontinued during the course of pegloticase therapy to avoid masking the loss of a pegloticase serum urate–lowering effect associated with an increased risk of pegloticase infusion reactions.

The TFP also weighed the rapidly emerging area of pharmacogenetics to screen for AHS (53,57,58), and recommended that, prior to initiation of allopurinol, HLA–B*5801 testing should be considered in select patient subpopulations at an elevated risk for AHS (evidence A). Those with HLA–B*5801 and of Korean descent with stage 3 or worse CKD (HLA–B*5801 allele frequency ~12%), or of Han Chinese or Thai extraction irrespective of renal function (HLA–B*5801 allele frequency ~6–8%), have been highlighted in the literature as prime examples of subjects at high risk for AHS, marked by HLA–B*5801 hazard ratios of several hundred (59–61). Such high-risk individuals were recommended to be prescribed an alternative to allopurinol if HLA–B*5801 positive (evidence A). The TFP recommended that the HLA–B*5801 screening be done by the rapid, widely available polymerase chain reaction (PCR)–based approach (evidence A) that, in only ~10% of tests, requires more cumbersome followup HLA–B*5801 sequencing for inconclusive results. Significantly, the TFP did not recommend universal HLA–B*5801 allopurinol screening. Current evidence informing this TFP decision included that whites with an HLA–B*5801 prevalence of ~2% had a substantially lower HLA–B*5801 hazard ratio and negative predictive value of the test than in the aforementioned Asian subpopulations (53,58,62).

Recommendations specific to primary uricosuric urate-lowering monotherapy. Under conditions where uricosuric monotherapy was employed as a primary ULT modality (Table 3), probenecid was recommended by the TFP as the first choice among uricosuric drugs currently available in the US (evidence B). The TFP recommended that a history of urolithiasis contraindicates first-line use of a potent uricosuric agent for ULT (evidence C), given that probenecid (and benzbromarone, which is unavailable in the US) was associated with an ~9–11% risk of urolithiasis (63,64). Specific TFP recommendations for risk management in uricosuric ULT also included initial measurement and monitoring of urine uric acid, and that an elevated urine uric acid level indicative of uric acid overproduction contraindicates uricosuric ULT. There was no TFP consensus on assay of undissociated urine uric acid, or use of Simkin's Index and similar calculation on spot urine, in risk management in uricosuric therapy (63). The TFP did recommend that when initiating uricosuric ULT, patients should also be instructed to increase fluid intake and consider urine alkalinization (e.g., with potassium citrate; evidence C for all) (63), but no quantitative parameters were voted on for these measures, in view of lack of evidence.

Recommendations on pharmacologic ULT decision making in gout, including case scenarios with mild, moderate, or severe disease activity or CTGA. The TFP voted on clinical decision making in each of the 9 case scenarios when the serum urate target had not yet been met and under circumstances where gout remained symptomatic (i.e., where there were 1 or more continuing clinical signs and symptoms of gout, such as recent acute gout attacks, tophi, and chronic gouty arthritis) (Figure 5 and Table 4). In doing so, the TFP, in limited voting scenarios, first considered the potential role of imaging in the evaluation of disease burden and clinical decision making on ULT gout. The TFP recommended the utility of high-resolution ultrasound, CT, or dual-energy CT (evidence B) to detect tophi, and the utility of plain radiographic findings consistent with tophi (such as characteristic bone erosion; evidence C). The TFP also voted that the ultrasound "double contour sign" was consistent with nontophaceous urate crystal deposition on the surface of articular cartilage (evidence B). However, the TFP did not recommend use of the double contour sign as a sufficient indicator for initiating or increasing the intensity of ULT, given that the sign was detected in joints of ~25% subjects with asymptomatic hyperuricemia in a recent study (65). Conversely, in a recent study, the double contour sign was not universally detectable (i.e., absent in ~33% of subjects in an ultrasound survey of multiple joints in each subject) in patients with early gout not receiving ULT (66).

For all 9 case scenarios when the serum urate target has not been met, the TFP recommended upward dose titration of 1 XOI (allopurinol or febuxostat) to the respective maximum appropriate dose for the individual patient (evidence A) (Figure 5 and Table 4). The maximum FDA-approved dose of allopurinol is 800 mg daily, and for febuxostat is 80 mg daily. Given the request for an international frame of the gout guidelines by the ACR, the TFP recommended increasing febuxostat up to 120 mg daily, a dose approved in many countries outside the US, in the specific scenario of active disease refractory to appropriately dosed oral ULT (evidence A). The TFP further recommended, and broadly so in the 9 case scenarios, that if upward titration of the initial XOI agent was not tolerated or did not achieve the serum urate target, substitution of another XOI was an appropriate first-line option (evidence C).

Notably, the TFP recommended probenecid and other agents with clinically significant uricosuric effects, such as fenofibrate and losartan, as therapeutically useful in a comprehensive ULT program in refractory disease (evidence B). Specifically, the TFP recommended a combination oral ULT approach (i.e., 1 XOI agent [allopurinol or febuxostat] and 1 uricosuric agent [probenecid, fenofibrate, or losartan being the currently available agents in the US]) as an option when the serum urate target has not been met across the 9 case scenarios (evidence B) (67–69) (Figure 5 and Table 4).

Last, the TFP recommended pegloticase as appropriate only in the case scenarios with severe gout disease burden and refractoriness to, or intolerance of, appropriately dosed oral ULT options (evidence A) (Figure 5 and Table 4). In 2 large placebo-controlled randomized clinical trials, pegloticase 8 mg every 2 weeks was effective in reducing the serum uric acid level to <6 mg/dl in 42% of patients versus 0% in the placebo group at 6 months (27). In addition, 45% of patients receiving pegloticase 8 mg every 2 weeks had complete resolution of 1 or more tophi versus 8% in the placebo group, with significant improvement in chronic arthropathy and health-related quality of life. Importantly, the TFP did not recommend pegloticase as a first-line ULT for any case scenarios. The TFP also did not

achieve consensus on the appropriate duration of pegloticase therapy once decreased symptoms and signs of gout, including decrease in size (or resolution) of tophi on clinical examination, had been achieved.

Discussion

We present the first ACR evidence- and consensus-based pharmacologic and nonpharmacologic management recommendations for gout, the product of a formal group consensus process. The thorough systematic review of the literature essential to this project was timely. Comparable gout guidelines independently (i.e., not developed with pharmaceutical company support) assembled at the level of national and multinational rheumatology societies in the last decade by EULAR and the BSR did not comprehensively evaluate newer evidence and therapies, including febuxostat and pegloticase (21,24). The ACR-sponsored work presented here in part 1 of the guidelines focused on systematic disease management and urate-lowering measures in all gout patients and in refractory disease, including CTGA. The work first addressed core aspects of patient education, which includes discussion with the patient of the role of uric acid excess in gout and as key long-term treatment target, and impacts heavily on ULT treatment adherence and ultimate efficacy (34). Based on the existing evidence in patients with gout, the TFP was able to generate a set of diet and lifestyle recommendations for gout, but the recommendations are dominated or superseded, for good reason, by diet and lifestyle recommendations for life-threatening comorbidities common in gout patients, such as atherosclerosis, diabetes mellitus, and hypertension. There was only limited advice on specific serving sizes and quantities, as was the case for prior gout recommendations of this nature (21). Clearly, more research is needed in diet and lifestyle modifications for gout, especially for direct intervention studies (34).

The TFP also recommended that all gout patients have a thorough clinical evaluation of disease activity and burden, and appropriate attention to possible etiologies of hyperuricemia in each patient, with potential modification of secondary causes of hyperuricemia such as comorbidities and specific medications that elevate serum urate. However, the TFP did not vote on specific indications for employing imaging studies to assess disease burden or treatment responses in gout. This issue should be updated in the next few years, as more studies appear on the use of high-resolution ultrasound and dual-energy CT that may inform disease classification and prognosis in gout, and as more outcomes data emerge on ULT-induced alterations in imaging findings of gout (70).

Specific TFP recommendations on indications for pharmacologic ULT initiation were accompanied by novel TFP recommendations that either allopurinol or febuxostat is appropriate as the first line of pharmacologic ULT, although the issue of allopurinol nontitration in comparison to clinical trial designs for these agents was recognized. Probenecid was recommended as an alternative first-line therapy if at least 1 XOI drug was contraindicated or not tolerated, but probenecid monotherapy was not recommended as a first-line approach in those with a creatinine clearance less than 50 ml/minute. In discussion, TFP reservations on probenecid included lack of data on long-term safety and efficacy in stage 3 CKD (given that creatinine clearance <50 ml/minute was an exclusion criterion in some studies [48,69]). Reservations also included multiple drug interactions, the ~9% risk of urolithiasis, and the complexity of risk management in dose escalation of probenecid ULT as a monotherapy. There was an unexpected lack of TFP consensus on ideal approaches to monitor uric acid excretion to lessen the risk of urolithiasis risk management during probenecid ULT as monotherapy.

Treating to a serum urate target was evaluated in detail. The TFP consolidated previous EULAR and BSR recommendations (21,24), here recommending that serum urate should be lowered in patients with gout to achieve, at a minimum, a serum urate level <6 mg/dl. In those with greater disease severity and urate burden, such as those with tophi detected on physical examination and with CTGA, the TFP recommended that the serum urate level may need to be lowered below 5 mg/dl to achieve better disease control.

Dosing, efficacy, and safety of allopurinol were addressed at length, since allopurinol is the most commonly prescribed ULT worldwide. First, TFP recommendations reinforced both the previous EULAR guidelines (21) and FDA guidance for risk management to initiate allopurinol at no more than 100 mg daily, and to start allopurinol at 50 mg daily in patients with stage 4 or worse CKD. Second, the TFP recommended steady upward titration of allopurinol soon after initiation, accompanied by adequate patient education and monitoring for drug toxicity. Recent clinical trial evidence that allopurinol doses of 300 mg or less daily fail to achieve target serum urate in the majority of gout patients informed the TFP recommendation that, with appropriate risk management, allopurinol can be advanced above 300 mg daily to achieve the serum urate target, including in patients with CKD. The TFP, for all degrees of renal impairment, did not recommend the AHS risk management strategy of Hande et al (56), in which a non–evidence-based algorithm for allopurinol maintenance dosing had been calibrated to renal impairment. However, the authors, without a specific TFP vote, are concerned about the lack of long-term safety data for allopurinol dosing above 300 mg daily, particularly with significant renal impairment, which is associated with increased allopurinol toxicity (50,71).

The TFP also made the novel recommendation that rapid PCR-based HLA–B*5801 screening should be considered as a risk management component in subpopulations where both the HLA–B*5801 allele frequency is elevated and the HLA–B*5801–positive subjects have a very high hazard ratio ("high risk") for severe allopurinol hypersensitivity reaction (e.g., Koreans with stage 3 [or worse] CKD and all those of Han Chinese and Thai descent). It is anticipated that additional high-risk subpopulations for AHS will be identified in future studies.

The TFP recommended uricosuric therapy as a valuable component of comprehensive urate-lowering strategies. Specific novel TFP recommendations on appropriateness of use of combination XOI and uricosuric ULT as a second-line approach in refractory disease across the case scenarios studied here reinforce BSR recommendations on such

a combination therapy (24). Significantly, for combination with an XOI drug, the TFP recommended not simply probenecid, but also as alternatives, other medications with less marked uricosuric effects (fenofibrate and losartan). However, the authors recognize that the published data are limited. The authors believe that ongoing and further studies will help understand how to optimize combinations of uricosuric agents with XOI therapy to decrease the risk of uricosuric-induced urolithiasis, while increasing the velocity of size reduction of body urate stores and tophi (67).

Based on results of placebo-controlled trials in study populations with particularly severe gout, the TFP recommended pegloticase as a third-line agent in distinct case scenarios of refractory disease with failure of appropriately dosed oral ULT, including in CTGA. Clinical trials directly comparing pegloticase to appropriate maximally dosed first- and second-line oral medication regimens of the agents recommended here would be of interest in severe gout, including CTGA.

Limitations of the ACR gout guidelines include the quality and quantity of evidence evaluated. For part 1 of the gout guidelines, the majority of evidence reviewed, upon which recommendations were based, was level C, with less than 20% level A evidence. For ULT clinical trials, study designs comparing allopurinol to febuxostat, where both agents are titrated to attempt to achieve the serum urate target, would be more informative than past trials (26,72,73). Another issue was variability in end points and outcome measures (e.g., gout attack frequency, serum urate, tophus size reduction, and health-related quality of life) in the clinical trials reviewed. Moreover, there are likely differences in "real-world" patients compared to those in most large industry-sponsored clinical trials. Clearly, further studies are needed in both the ULT and CTGA domains of gout.

The RAND/UCLA methodology utilized for this project did not allow us to address the important clinical practice and societal implications of treatment costs, which clearly impact patient and provider preferences for gout management options recommended by the TFP as effective. For example, the authors recognize the potential cost issues of the ULT recommendations presented, since, for example, febuxostat is substantially more expensive than allopurinol or probenecid. We note that a recent single technology appraisal with cost analysis done by an independent evidence review group of the National Institute for Health and Clinical Excellence concluded that febuxostat should be recommended for ULT in gout only in patients with contraindications or intolerance to allopurinol (25). Conversely, PCR-based HLA–B*5801 pharmacogenetics screening for allopurinol is a one-time test and relatively inexpensive, but raises new questions about the added costs to gout management, particularly for populations where the risk of AHS is low (53,57,58). Last, third-line ULT with pegloticase is an expensive biologic therapy approach for gout, and additional biologic agents for gout therapy are currently being developed and investigated. Cost-effectiveness trials and analyses are particularly timely for emerging therapies in gout.

The ACR guidelines for ULT in gout presented herein, and for treatment and antiinflammatory prophylaxis of gouty arthritis presented in a separate article (part 2 of the guidelines) (17), will require updating as new evidence emerges for appropriate evaluation and management of gout advances and new medications achieve regulatory agency approval. Increased comparative studies of gout-specific health-related quality of life impairment and disease activity outcomes for ULT agents and regimens evaluated here will be of particular interest, given cost, long-term safety, and other considerations such as cardiovascular disease outcomes. It is hoped that publication of these guidelines, along with effective patient education in gout treatments and the objectives and safety issues of management, will improve patient adherence, quality of care, and outcomes in management of gout.

Addendum. Therapies that were approved after the original literature review, or diet and lifestyle measures studied after the original literature review, are not included in these recommendations.

ACKNOWLEDGMENTS

We thank Ms Amy Miller and Ms Regina Parker of the ACR for administrative support and guidance. Drs. Jennifer Grossman (UCLA), Michael Weinblatt (Brigham and Women's Hospital, Harvard Medical School), Ken Saag (University of Alabama, Birmingham), and Ted Ganiats (University of California, San Diego) provided valuable guidance on the objectives and process. Rikke Ogawa (UCLA) provided greatly appreciated service as a medical research librarian.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Dr. Terkeltaub had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study conception and design. Dinesh Khanna, Fitzgerald, Puja P. Khanna, Bae, Neogi, Pillinger, Merill, Lee, Prakash, Perez-Ruiz, Choi, Jasvinder A. Singh, Dalbeth, Kaplan, Mandell, Schumacher, Robbins, Wenger, Terkeltaub.

Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide guidance for particular patterns of practice and not to dictate the care of a particular patient. The ACR considers adherence to these guidelines and recommendations to be voluntary, with the ultimate determination regarding their application to be made by the physician in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed or endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice.

The American College of Rheumatology is an independent, professional, medical and scientific society which does not guarantee, warrant, or endorse any commercial product or service.

Introduction

In response to a request for proposal from the American College of Rheumatology (ACR), our group was charged with developing nonpharmacologic and pharmacologic guidelines for treatments in gout that are safe and effective, i.e., with an acceptable risk/benefit ratio. These guidelines for the management and antiinflammatory prophylaxis of acute attacks of gouty arthritis complement our article on

Supported by a research grant from the American College of Rheumatology and by the National Institute of Arthritis and Musculoskeletal and Skin Diseases, NIH (grant K24-AR-063120).

Significance & Innovations

- An acute gouty arthritis attack should be treated with pharmacologic therapy, initiated within 24 hours of onset.
- Established pharmacologic urate-lowering therapy should be continued, without interruption, during an acute attack of gout.
- Nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroids, or oral colchicine are appropriate first-line options for treatment of acute gout, and certain combinations can be employed for severe or refractory attacks.
- Pharmacologic antiinflammatory prophylaxis is recommended for all gout patients when pharmacologic urate lowering is initiated, and should be continued if there is any clinical evidence of continuing gout disease activity and/or the serum urate target has not yet been achieved.
- Oral colchicine is an appropriate first-line gout attack prophylaxis therapy, including with appropriate dose adjustment in chronic kidney disease and for drug interactions, unless there is a lack of tolerance or medical contraindication.
- Low-dose NSAID therapy is an appropriate choice for first-line gout attack prophylaxis, unless there is a lack of tolerance or medical contraindication.

guidelines to treat hyperuricemia in patients with evidence of gout (or gouty arthritis) (1).

Gout is the most common cause of inflammatory arthritis in adults in the US. Clinical manifestations in joints and bursa are superimposed on local tissue deposition of monosodium urate crystals. Acute gout characteristically presents as a self-limited attack of synovitis (also called "gout flare"). Acute gout attacks account for a major component of the reported decreased health-related quality of life in patients with gout (2,3). Acute gout attacks can be debilitating and are associated with decreased work productivity (4,5).

Urate-lowering therapy (ULT) is a cornerstone in the management of gout (1) and, when effective in lowering serum urate, is associated with a decreased risk of acute gouty attacks (6). However, during the initial phase of ULT, there is an early increase in acute gout attacks, which has been hypothesized due to remodeling of articular urate crystal deposits as a result of rapid and substantial lowering of ambient urate concentrations (7). Acute gout attacks attributable to the initiation of ULT may contribute to nonadherence in long-term gout treatment, as reported in recent studies (8).

In order to systematically evaluate management of acute gouty arthritis, we generated multifaceted case scenarios to elucidate decision making based primarily on clinical and laboratory test–based data that can be obtained from a gout patient by both nonspecialist and specialist health care providers in an office practice setting. This effort was not intended to create a novel classification system of gout or new gout diagnostic criteria, since such endeavors are beyond the scope of this work.

Prior gout recommendations and guidelines, at the independent (i.e., non–pharmaceutical industry sponsored) national or multinational rheumatology society level, have

Submitted for publication January 9, 2012; accepted in revised form June 15, 2012.

been published by the European League Against Rheumatism (EULAR) (9,10), the Dutch College of General Practitioners (11), and the British Society for Rheumatology (BSR) (12). The ACR requested new guidelines in view of the increasing prevalence of gout (13), the clinical complexity of management of gouty arthritis imposed by comorbidities common in patients with gout (14), and increasing numbers of treatment options via clinical development of agents (15–17). The ACR charged us to develop these guidelines to be useful for both rheumatologists and other health care providers on an international level. As such, this process and resultant recommendations involved a diverse and international panel of experts.

In this article, we concentrate on 2 of the 4 gout domains (1) that the ACR requested for evaluation of pharmacologic and nonpharmacologic management approaches: analgesic and antiinflammatory management of acute attacks of gouty arthritis and pharmacologic antiinflammatory prophylaxis of acute attacks of gouty arthritis. Part 1 of the guidelines focused on systematic nonpharmacologic measures (patient education, diet and lifestyle choices, identification and management of comorbidities) that impact hyperuricemia, and made recommendations on pharmacologic ULT in a range of case scenarios of patients with disease activity manifested by acute and chronic forms of gouty arthritis, including chronic tophaceous gouty arthropathy (1). Each individual and specific statement is designated as a "recommendation," in order to reflect the nonprescriptive nature of decision making for the hypothetical clinical scenarios.

So that the voting panel could focus on gout treatment decisions, a number of key assumptions were made, as described in part 1 of the guidelines (1). Importantly, each proposed recommendation assumed that correct diagnoses of gout and acute gouty arthritis attacks had been made for the voting scenario in question. For treatment purposes, it was also assumed that treating clinicians were competent, and considered underlying medical comorbidities (including diabetes mellitus, gastrointestinal disease, hypertension, and hepatic, cardiac, and renal disease) and potential drug toxicities and drug–drug interactions when making both treatment choices and dosing decisions on chosen pharmacologic interventions. The RAND/University of California at Los Angeles (UCLA) methodology used here emphasizes the level of evidence, safety, and quality of therapy, and excludes analyses of societal cost of health care. As such, the ACR gout guidelines are designed to reflect best practice, supported either by level of evidence or consensus-based decision making. These guidelines cannot substitute for individualized direct assessment of the patient, coupled with clinical decision making by a competent health care practitioner. The motivation, financial circumstances, and preferences of the gout patient also need to be considered in clinical practice, and it is incumbent on the treating clinician to weigh the issues not addressed by this methodology, such as treatment costs, when making management decisions. Last, the guidelines for gout management presented herein were not designed to determine eligibility for health care cost coverage by third party payors.

Materials and methods

Utilizing the RAND/UCLA methodology (18), we conducted a systematic review, generated case scenarios, developed recommendations, and graded the evidence.

Design: RAND/UCLA Appropriateness Method overview. The RAND/UCLA method of group consensus was developed in the 1980s, incorporates both Delphi and nominal group methods (18), and has been successfully used to develop other guidelines commissioned by the ACR. The purpose of this methodology is to reach a consensus among experts, with an understanding that published literature may not be adequate to provide sufficient evidence for day-to-day clinical decision making. The RAND/UCLA method requires 2 groups of experts: a core expert panel (CEP) that provides input into case scenario development, and a task force panel (TFP) that votes on the case scenarios (1). A systematic review of pertinent literature was performed concurrently, and a scientific evidence report was generated. This evidence report was then given to the TFP, in conjunction with a variety of clinical scenarios and clinical decision-making questions of interest for each scenario.

The diverse TFP, totaling 11 people, consisted of rheumatologists in a community private practice (CK), a health maintenance organization practice (GL), and a Veterans Affairs practice (GK); a rheumatology physician–scientist inflammation researcher (BR); a rheumatologist with expertise in clinical pharmacology (DEF); a rheumatologist gout expert that is an Internal Medicine Residency Director (NLE); a rheumatologist gout expert that is a Chair of Internal Medicine (BM); 2 primary care internal medicine physicians (DJ, SAY); a nephrologist (VN); and a patient representative (SK) (1). There were 2 rounds of ratings, the first anonymous, with the members of the TFP instructed to rank each potential element of the guidelines on a risk/benefit Likert scale ranging from 1–9, followed by a face-to-face group discussion with revoting. A vote of 1–3 on the Likert scale was scored as *inappropriate*, where risks clearly outweigh the benefits; a vote of 4–6 was scored as *uncertain* ("lack of consensus"), where the risk/benefit ratio is uncertain; and a vote of 7–9 was scored as *appropriate*, where benefits clearly outweigh the risks. Case scenarios were translated into recommendations, where the median voting scores were 7–9 on the Likert scale ("appropriate"), and if there was no significant disagreement, defined as no more than one-third of the TFP voting below the Likert scale level of 7 in the question. The final rating was done anonymously in a 2-day face-to-face meeting led by an experienced internal medicine physician moderator (NW).

Systematic review. PubMed and the Cochrane Central Register of Controlled Trials (CENTRAL) were searched to find all articles on gout with the help of an experienced librarian. PubMed is a database of medical literature from the 1950s to the present. CENTRAL includes references from PubMed, Embase, and the Cochrane Review Groups' specialized registers of controlled trials and hand search results. We used search terminology (hedge) based on the Cochrane Highly Sensitive Search Strategy for identifying

randomized trials. The hedge was expanded to include articles discussing research design, cohort, case–control, and cross-sectional studies. Limits added to the hedge include English language and the exclusion of "animal only" studies. The searches for all 4 domains were conducted simultaneously and therefore included terms for hyperuricemia and other gout-related issues. Conducted on September 25, 2010, the search retrieved 5,830 articles from PubMed and CENTRAL. The review was divided into 3 stages: titles, abstracts from manuscripts, and entire manuscripts. At each stage, each title, abstract, or manuscript was included or excluded using prespecified rules, as described (1). Of the 5,830 titles, 192 duplicate titles and 82 non-English titles were excluded, with an additional 3,729 titles excluded based on exclusion criteria, leaving 1,827 titles, of which another 1,699 were excluded in the abstract phase. A total of 128 manuscripts remained that were further categorized into pharmacologic and nonpharmacologic studies (1). Subsequently, we updated our systematic review by repeating the search with the same criteria to include any articles that were published between September 25, 2010 and March 31, 2011, and we hand searched recent meeting abstracts from the ACR and EULAR for any randomized controlled trials that were yet to be published. The supplemental search resulted in 4 additional manuscripts and 5 meeting abstracts on pharmacologic agents, some of which were subsequently published and then reevaluated for evidence grade. Finally, there were 41 manuscripts on nonpharmacologic modalities (such as diet, alcohol, exercise, etc.) that included both retrospective and prospective studies, but all were excluded, since none were randomized controlled studies on interventions in gout patients. There were 87 manuscripts on pharmacologic agents for the treatment of patients with gout. Of these, 47 were randomized controlled trials and included in the evidence report, whereas the remaining 40 uncontrolled trials were excluded. A total of 21 manuscripts on ULT were separately addressed (1).

For this article (part 2 of the guidelines), a total of 30 manuscripts and 5 meeting abstracts were assessed, with 26 manuscripts and 2 meeting abstracts on acute gout and 4 manuscripts and 3 meeting abstracts on prophylaxis included in the evidence report and evaluated by the TFP.

Case scenarios. Through an interactive, iterative process, the CEP developed unique case scenarios of acute gouty attacks with varied treatment options, and the type of attack by severity, duration, and extent of the attack. The objective was to represent a broad spectrum of attacks that a clinician might see in a busy practice. For the case scenarios, the severity of acute gout differed based on self-reported worst pain on a 0–10 visual analog scale (VAS) (19,20). Pain ≤4 was considered mild, 5–6 was considered moderate, and ≥7 was considered severe (19,20). Case scenarios also varied by duration of the acute gout attack; we divided this into early (<12 hours), well established (12–36 hours), and late (>36 hours). Case scenarios also varied in the number of active joints involved: 1 or a few small joints, 1 or 2 large joints (ankle, knee, wrist, elbow, hip, or shoulder), and polyarticular involvement (defined as either acute arthritis involving 3 separate large joints, or acute arthritis of 4 or more joints, with arthritis involving more than 1 "region" of joints). Joint regions were defined as: forefoot (metatarsal joints and toes), midfoot (tarsal joints), ankle/hindfoot, knee, hip, fingers, wrist, elbow, shoulder, or other (Figure 1). The management strategies presented were developed for case scenarios involving gouty arthritis, but the intent was that acute bursal inflammation due to gout (e.g., in the prepatellar or olecranon bursa) and small joint involvement would have comparable recommendations for overall management strategies.

Developing recommendations from votes by the TFP and grading the evidence. A priori recommendations were derived from only positive results (median Likert score ≥7). In the text below, all recommendations derived from TFP votes are denoted by an accompanying evidence grade. In addition to TFP vote results, the panel provided some statements based on discussion (not votes). Such statements are specifically described as discussion items (rather than TFP-voted recommendations) in the Results. We also comment on specific circumstances where the TFP did not vote a particularly important clinical decision-making item as appropriate (i.e., the median Likert score was ≤6 or there was a wide dispersion of votes despite a median score of ≥7). Samples of voting scenarios and results are shown in Supplemental Figure 1 (available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658).

The level of evidence supporting each recommendation was ranked based on previous methods used by the American College of Cardiology (21) and applied to other recent ACR recommendations (22,23): level A grading was assigned to recommendations supported by more than 1 randomized clinical trial, or 1 or more meta-analyses; level B grading was assigned to the recommendations derived from a single randomized trial, or nonrandomized studies; and level C grading was assigned to consensus opinion of experts, case studies, or standard of care.

Managing perceived potential conflict of interest (COI). Potential COI was managed in a prospective and structured manner (1). All of the participants intellectually involved in the project, whether authors or not, were required to fully disclose their relationships with any of the companies with a material interest in gout, listed in Supplemental Appendix A (available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658). Disclosures were identified at the start of the project and updated every 6 months. A summary listing of all perceived potential COI is available in Supplemental Appendix A (available in the online version of this article at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)2151-4658).

Based on the policies of the ACR, no more than 49% of the project participants were permitted to have COI at any given time, and a majority of the TFP was required to have no perceived potential COI. It was further required that the project principal investigator (JDF) remain without per-

Severity of Acute Gouty Arthritis Attack Intensity of attack based on self-reported pain (0-10 visual analog scale)	
Mild	≤ 4
Moderate	5-6
Severe	≥ 7

Duration of the gouty arthritis attack since onset	
Early	< 12 Hours after attack onset
Well-Established	12 to 36 Hours after attack onset
Late	> 36 Hours after attack onset

Extent of acute gouty arthritis attack Based on number of active joints
One or a few small joints
1 or 2 large* joints * *defined as: ankle, knee, wrist, elbow, hip, shoulder*
Polyarticular • 4 or more joints, with arthritis involving more than 1 region§ § *Regions defined as: forefoot (metatarsophalangeal joints, toes), midfoot (tarsal joints), ankle/hindfoot, knee, hip, fingers, wrist, elbow, shoulder, other* • Acute gout attack involving 3 separate large joints is considered as a form of polyarticular gout for this scheme of management

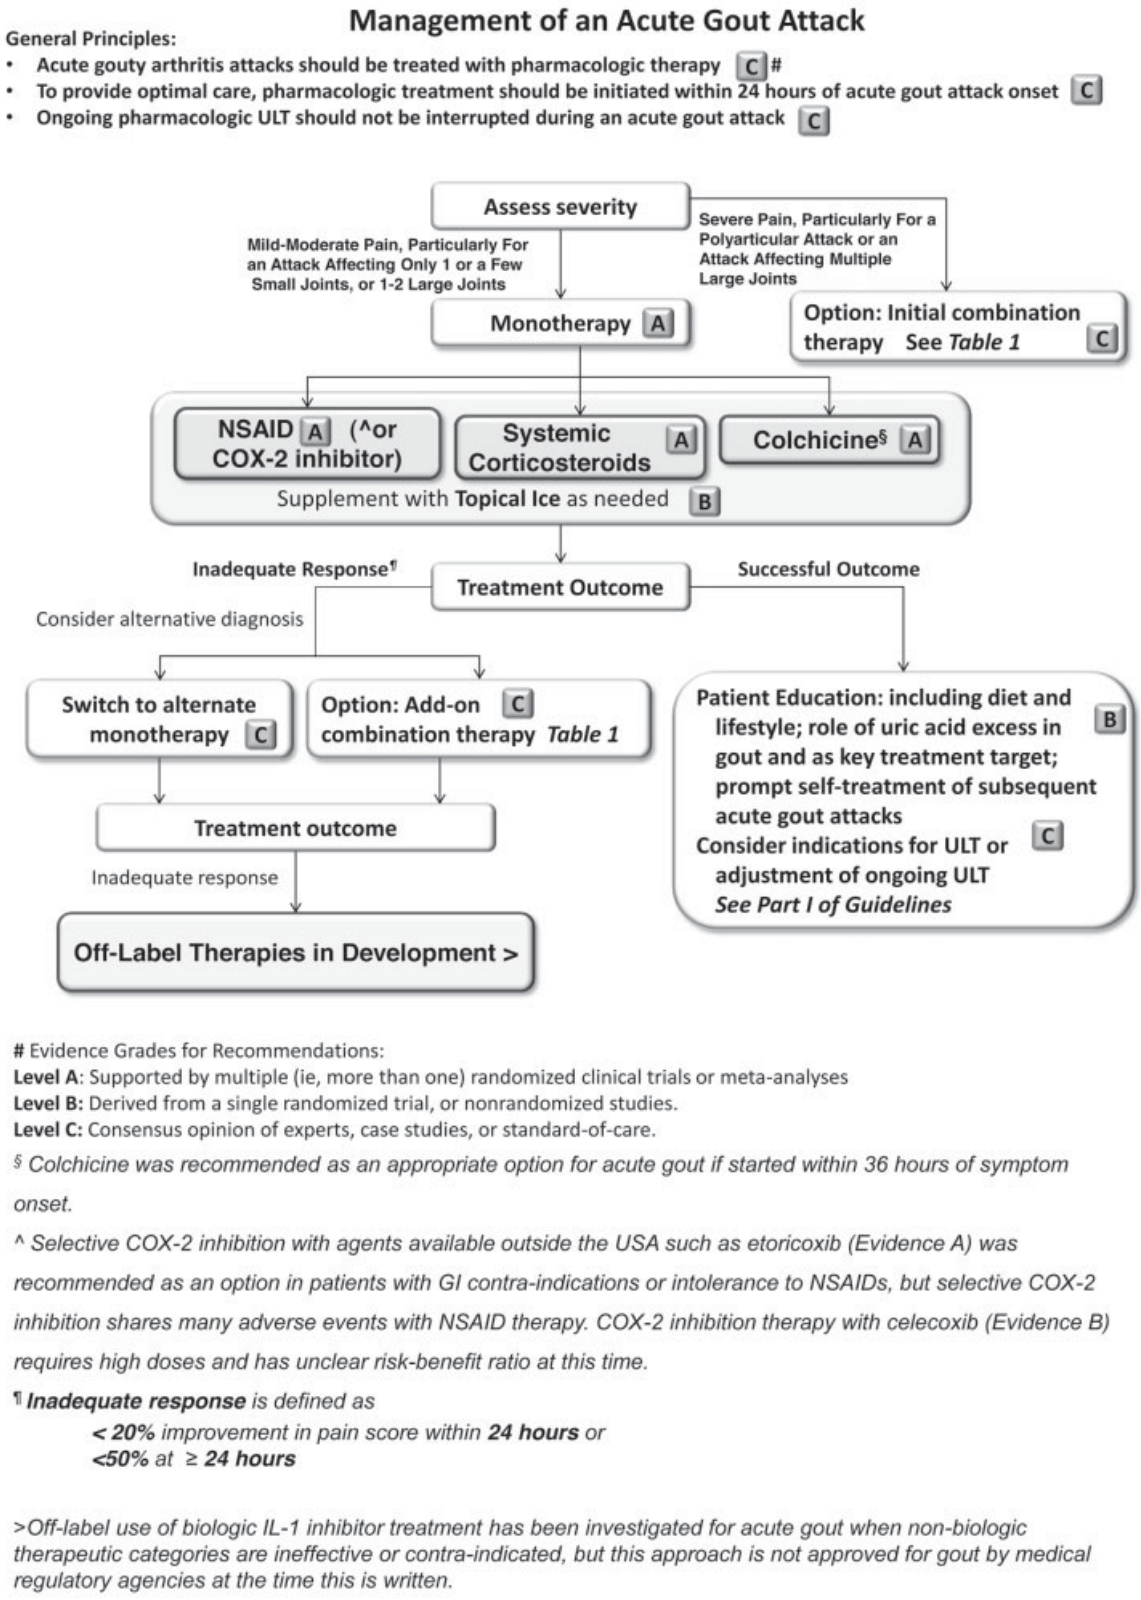
Figure 1. Case scenarios for defining acute gouty arthritis attack features. These case scenarios were generated by the core expert panel, and therapeutic decision-making options for these scenarios were voted on by the task force panel.

ceived potential COI during the guideline development process, and for an additional 12 months afterward.

Results

General principles for treatment of the acute attack of gouty arthritis ("acute gout" management). Figure 2 summarizes the overall recommendations on treatment of an acute gouty arthritis attack. The TFP recommended that an acute gouty arthritis attack should be treated with pharmacologic therapy (evidence C), and that treatment should be preferentially initiated within 24 hours of onset of an acute gout attack (evidence C). The latter recommendation was based on consensus that early treatment leads to better patient-reported outcomes. The TFP also recommended continuing established pharmacologic ULT without interruption during an acute attack of gout (evidence C), i.e., do not stop ULT therapy during an acute attack. The TFP also recommended patient education, not simply on dietary and other triggers of acute gout attacks, but also providing the patients with instruction so that they can initiate treatment upon signs and symptoms of an acute gout attack, without the need to consult their health care practitioner for each attack (evidence B) (24). Moreover, fundamental patient education includes discussion that gout is caused by body excess of uric acid, and that only effective ULT is potentially "curative" (evidence B) (24).

Initial pharmacologic treatment of the acute attack of gouty arthritis. The TFP recommended that the choice of pharmacologic agent should be based upon severity of pain and the number of joints involved (Figure 2). For attacks of mild/moderate gout severity (≤6 of 10 on a 0–10 pain VAS) particularly those involving 1 or a few small joints or 1 or 2 large joints, the TFP recommended that initiating monotherapy was appropriate, with recommended options being oral nonsteroidal antiinflammatory drugs (NSAIDs), systemic corticosteroids, or oral colchicine (evidence A for all therapeutic categories) (25–28) (Figure 2). The TFP also voted that combination therapy was an appropriate option to consider when the acute gout attack was characterized by severe pain, particularly in an acute polyarticular gout attack or an attack involving 1–2 large joints (evidence C) (Figure 2). The TFP did not rank one therapeutic class over another. Therefore, it is at the discretion of the prescribing physicians to choose the most appropriate monotherapy based on the patient's preference, prior response to pharmacologic therapy for an acute gout attack, and associated comorbidities. Recommendations for appropriate combination therapy options are highlighted in Table 1 and discussed below. The TFP did not vote on case scenarios for specific renal or hepatic function impairment–adjusted dosing and individual contraindications or drug–drug interactions with pharmacologic therapies (29–31).



Management of an Acute Gout Attack
General Principles:
• Acute gouty arthritis attacks should be treated with pharmacologic therapy C #
• To provide optimal care, pharmacologic treatment should be initiated within 24 hours of acute gout attack onset C
• Ongoing pharmacologic ULT should not be interrupted during an acute gout attack C
Assess severity
Mild-Moderate Pain, Particularly For an Attack Affecting Only 1 or a Few Small Joints, or 1-2 Large Joints
Severe Pain, Particularly For a Polyarticular Attack or an Attack Affecting Multiple Large Joints
Monotherapy A
Option: Initial combination therapy See Table 1 C
NSAID A (^or COX-2 inhibitor)
Systemic Corticosteroids A
Colchicine§ A
Supplement with Topical Ice as needed B
Inadequate Response¶
Treatment Outcome
Successful Outcome
Consider alternative diagnosis
Switch to alternate monotherapy C
Option: Add-on C combination therapy Table 1
Patient Education: including diet and lifestyle; role of uric acid excess in gout and as key treatment target; prompt self-treatment of subsequent acute gout attacks B
Consider indications for ULT or adjustment of ongoing ULT C
See Part I of Guidelines
Treatment outcome
Inadequate response
Off-Label Therapies in Development >
Evidence Grades for Recommendations:
Level A: Supported by multiple (ie, more than one) randomized clinical trials or meta-analyses
Level B: Derived from a single randomized trial, or nonrandomized studies.
Level C: Consensus opinion of experts, case studies, or standard-of-care.
§ Colchicine was recommended as an appropriate option for acute gout if started within 36 hours of symptom onset.
^ Selective COX-2 inhibition with agents available outside the USA such as etoricoxib (Evidence A) was recommended as an option in patients with GI contra-indications or intolerance to NSAIDs, but selective COX-2 inhibition shares many adverse events with NSAID therapy. COX-2 inhibition therapy with celecoxib (Evidence B) requires high doses and has unclear risk-benefit ratio at this time.
¶ Inadequate response is defined as
< 20% improvement in pain score within 24 hours or
<50% at ≥ 24 hours
>Off-label use of biologic IL-1 inhibitor treatment has been investigated for acute gout when non-biologic therapeutic categories are ineffective or contra-indicated, but this approach is not approved for gout by medical regulatory agencies at the time this is written.

Figure 2. Overview of management of an acute gout attack. This algorithm summarizes the recommendations by the task force panel on the overall approach to management of an acute attack of gouty arthritis, with further details, as expanded in other figures and tables, referenced in the figure and discussed in the text. ULT = urate-lowering therapy; NSAID = nonsteroidal antiinflammatory drug; COX-2 = cyclooxygenase 2; GI = gastrointestinal; IL-1 = interleukin-1.

Table 1. Task force panel (TFP) recommendations for combination therapy approach to acute gouty arthritis

Initial combination therapy is an appropriate option for an acute, severe gout attack, particularly with involvement of multiple large joints or polyarticular arthritis (evidence C)
Acceptable combination therapy approaches include the initial simultaneous use of full doses (or, where appropriate, prophylaxis doses) of either: 1) colchicine and nonsteroidal antiinflammatory drugs (NSAIDs), 2) oral corticosteroids and colchicine, or 3) intra-articular steroids with all other modalities (evidence C)
For patients not responding adequately to initial pharmacologic monotherapy, adding a second appropriate agent is an acceptable option (evidence C)*
The TFP was not asked to vote on use of NSAIDs and systemic corticosteroids in combination, given core expert panel concerns about synergistic gastrointestinal tract toxicity

* Assumes that the initial diagnosis of acute gout was correct, and that the lack of adequate response of acute gout was to an appropriate first-line therapy option.

NSAIDs. For NSAIDs, the TFP recommended full dosing at either the Food and Drug Administration (FDA)– or European Medical Agency–approved antiinflammatory/analgesic doses used for the treatment of acute pain and/or treatment of acute gout (evidence A–C) (27,28,32–34) (Figure 3A). The FDA has approved naproxen (evidence A) (34,35), indomethacin (evidence A) (27,28,32,33), and sulindac (evidence B) (36) for the treatment of acute gout. However, analgesic and antiinflammatory doses of other NSAIDs may be as effective (evidence B and C). For cyclooxygenase 2 (COX-2) inhibitors, as an option in patients with gastrointestinal contraindications or intolerance to NSAIDs, published randomized controlled trials support the efficacy of etoricoxib (evidence A) and lumiracoxib (evidence B) (25,37,38), but these agents are not available in the US, and lumiracoxib has been withdrawn from use in several countries due to hepatotoxicity. A randomized controlled trial of a single comparison of celecoxib versus indomethacin (39) suggested effectiveness of a high-dose celecoxib regimen (800 mg once, followed by 400 mg on day 1, then 400 mg twice daily for a week) in acute gout. The TFP recommended this celecoxib regimen as an option for acute gout in carefully selected patients with contraindications or intolerance to NSAIDs (evidence B), keeping in mind that the risk/benefit ratio is not yet clear for celecoxib in acute gout.

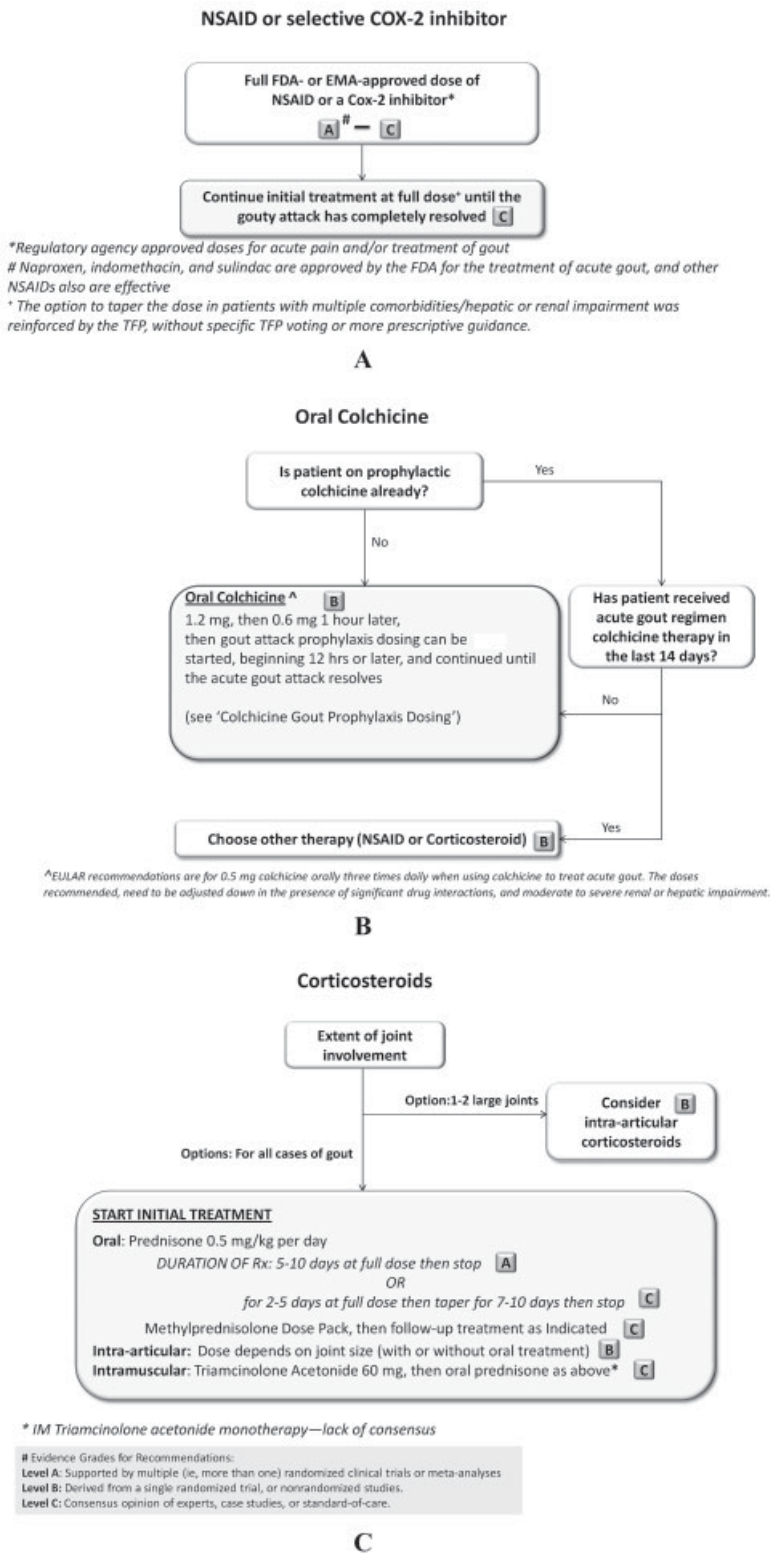
The TFP did not reach a consensus to preferentially recommend any one specific NSAID as first-line treatment. The TFP did recommend continuing the initial NSAID inhibitor treatment regimen at the full dose (if appropriate) until the acute gouty attack completely resolved (evidence C). The option to taper the dose in patients with multiple comorbidities/hepatic or renal impairment was reinforced by the TFP, without specific TFP voting or more prescriptive guidance. Last, there was no TFP consensus on the use of intramuscular ketorolac or topical NSAIDs for the treatment of acute gout.

Colchicine. The TFP recommended oral colchicine as one of the appropriate primary modality options to treat acute gout, but only for gout attacks where the onset was no greater than 36 hours prior to treatment initiation (evidence C) (Figure 3B). The TFP recommended that acute gout can be treated with a loading dose of 1.2 mg of colchicine followed by 0.6 mg 1 hour later (evidence B) (10), and this regimen can then be followed by gout attack prophylaxis dosing 0.6 mg once or twice daily (unless dose adjustment is required) 12 hours later, until the gout attack resolves (evidence C) (26). For countries where 1.0 mg or 0.5 mg rather than 0.6 mg tablets of colchicine are available, the TFP recommended, as appropriate, 1.0 mg colchicine as the loading dose, followed by 0.5 mg 1 hour later, and then followed, as needed, after 12 hours, by continued colchicine (up to 0.5 mg 3 times daily) until the acute attack resolves (evidence C). In doing so, the TFP rationale was informed by pharmacokinetics of the low-dose colchicine regimen, where the exposure to the drug in plasma becomes markedly reduced ~12 hours after administration in healthy volunteers (26). The TFP also evaluated prior EULAR recommendations on a colchicine dosing regimen for acute gout (0.5 mg 3 times daily) and the BSR-recommended maximum dosage for acute gout of 2 mg colchicine per day (10,12).

The algorithm in Figure 3B outlines recommendations for colchicine based on FDA labeling and TFP deliberations and votes, including specific recommendations for patients already receiving colchicine acute gout attack prophylaxis. For more specific prescriptive guidance, practitioners should consult the FDA-approved drug labeling, including recommended dosing reduction in moderate to severe chronic kidney disease (CKD) (40,41), and colchicine dose reduction (or avoidance of colchicine use) with drug interactions with moderate to high potency inhibitors of cytochrome P450 3A4 and of P-glycoprotein; major colchicine drug interactions include those with clarithromycin, erythromycin, cyclosporine, and disulfiram (30,31). Last, the TFP did not vote on use of intravenous colchicine, since the formulation is no longer available in the US, due to misuse and associated severe toxicity.

Systemic and intraarticular corticosteroids and adrenocorticotropic hormone (ACTH). When selecting corticosteroids as the initial therapy, the TFP recommended to first consider the number of joints with active arthritis. For involvement of 1 or 2 joints, the TFP recommended the use of oral corticosteroids (evidence B); the TFP additionally recommended the option of intraarticular corticosteroids for acute gout of 1 or 2 large joints (evidence B) (42) (Figure 3C). For intraarticular corticosteroid therapy in acute gouty arthritis, it was recommended that dosing be based on the size of the involved joint(s), and that this modality could be used in combination (Table 1) with oral corticosteroids, NSAIDs, or colchicine (evidence B) (42). Specific doses for intraarticular corticosteroid therapy in specific joints were not considered during TFP voting.

Where intraarticular joint injection is impractical (e.g., polyarticular joint involvement, patient preference, or injection of the involved joint site is not in the scope of the provider's usual practice), the TFP recommended oral cor-



NSAID or selective COX-2 inhibitor
Full FDA- or EMA-approved dose of NSAID or a Cox-2 inhibitor*

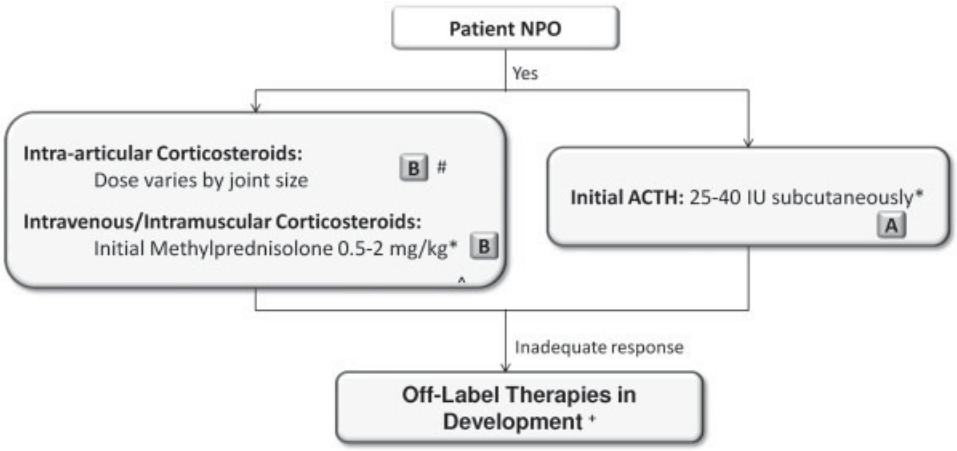
Figure 3. Recommendations for the individual pharmacologic monotherapy options for an acute gouty arthritis attack. The figure is separated into distinct parts that schematize use of the first-line therapy options (**A,** nonsteroidal antiinflammatory drugs [NSAIDs], **B,** colchicine, and **C,** corticosteroids), and specific recommendations by the task force panel (TFP). COX-2 = cyclooxygenase 2; FDA = Food and Drug Administration; EMA = European Medical Agency; EULAR = European League Against Rheumatism; IM = intramuscular.

ticosteroids, prednisone, or prednisolone at a starting dosage of at least 0.5 mg/kg per day for 5–10 days, followed by discontinuation (evidence A) (28,43), or alternately, 2–5 days at the full dose, followed by tapering for 7–10 days, and then discontinuation (evidence C). Acknowledging current prevalence of usage, the TFP recommended, as an



** Can be repeated. Subsequent dose will be determined based on initial response.*

^Lack of consensus: IM Triamcinolone acetonide monotherapy, and IM Ketorolac NSAID therapy.

+ Off-label biologic IL-1 inhibitor treatment, such as with anakinra, has not been approved by medical regulatory agencies for gout at the time this is written, and has unclear risk-benefit ratio.

Evidence Grades for Recommendations:
Level A: Supported by multiple (ie, more than one) randomized clinical trials or meta-analyses
Level B: Derived from a single randomized trial, or nonrandomized studies.
Level C: Consensus opinion of experts, case studies, or standard-of-care.

Figure 4. Acute gouty arthritis attack management in the nothing by mouth (NPO) patient. The figure schematizes options for management of acute gout in the patient unable to take oral antiinflammatory medications, and specific recommendations by the task force panel on decision making in this setting. ACTH = adrenocorticotropic hormone; IL-1 = interleukin-1; IM = intramuscular; NSAID = nonsteroidal antiinflammatory drug.

appropriate option according to provider and patient preference, the use of an oral methylprednisolone dose pack for initial treatment of an acute attack of gout (evidence C).

The TFP also recommended, as appropriate in each case scenario, an alternative regimen of intramuscular single-dose (60 mg) triamcinolone acetonide, followed by oral prednisone or prednisolone (evidence C). However, there was no consensus by the TFP on the use of intramuscular triamcinolone acetonide as monotherapy. Last, the TFP vote also did not reach a consensus on use of ACTH (evidence A) for acute gout in patients able to take medications orally, but did consider ACTH in separate voting, as described below, for patients unable to take oral antiinflammatory medications.

Initial combination therapy for acute gout. For patients with severe acute gout attack (≥7 of 10 on a 0–10 pain VAS) and patients with an acute polyarthritis or involvement of more than 1 large joint, the TFP recommended, as an appropriate option, the initial simultaneous use of full doses (or, where appropriate, a full dose of 1 agent and prophylaxis dosing of the other) of 2 of the pharmacologic modalities recommended above. Specifically, the TFP recommended the option to use combinations of colchicine and NSAIDs, oral corticosteroids and colchicine, or intra-articular steroids with any of the other modalities (evidence C). The TFP was not asked by the CEP to vote on use of NSAIDs and systemic corticosteroids in combination, given CEP concerns about synergistic gastrointestinal tract toxicity of that drug combination.

Inadequate response of an acute gout attack to initial therapy. There is a lack of a uniform definition of an inadequate response to the initial pharmacologic therapy for an acute attack of gouty arthritis (2,26,44). Clinical trials in acute gout have defined variable primary end points for therapeutic response, such as percent improvement in pain on a Likert scale or VAS. To define inadequate response for scenarios in this section, the CEP asked the TFP to vote on various percent improvement definitions at time points such as 24, 48, or 72 hours. The TFP voted that the following criteria would define an inadequate response of acute gout to pharmacologic therapy in case scenarios: either <20% improvement in pain score within 24 hours or <50% improvement in pain score ≥24 hours after initiating pharmacologic therapy.

For the scenario of a patient with an acute attack of gouty arthritis not responding adequately to initial pharmacologic monotherapy, the TFP advised, without a specific vote, that alternative diagnoses to gout should be considered (Figure 2 and Table 1). For patients not responding to initial therapy, the TFP also recommended switching to another monotherapy recommended above (evidence C) or adding a second recommended agent (evidence C). Use of a biologic interleukin-1 (IL-1) inhibitor (anakinra 100 mg subcutaneously daily for 3 consecutive

days; evidence B) (44,45) or canakinumab 150 mg subcutaneously (46,47) as an option for severe attacks of acute gouty arthritis refractory to other agents was graded as evidence A in the systematic review. Given a lack of randomized studies for anakinra (44,45) and the unclear risk/benefit ratio and lack of FDA approval for canakinumab (46,47) at the time this was written, the authors, independent of TFP discussion, assessed the role of IL-1 inhibitor therapy in acute gout as uncertain.

Case scenarios for the nothing by mouth (NPO) patient. Acute gout attacks are common in the in-hospital setting, where patients may be NPO due to different surgical and medical conditions. In such a scenario, the TFP recommended intraarticular injection of corticosteroids for involvement of 1 or 2 joints (with the dose depending on the size of the joint; evidence B) (42) (Figure 4). The TFP also recommended, as appropriate options, intravenous or intramuscular methylprednisolone at an initial dose at 0.5–2.0 mg/kg (evidence B) (48).

The TFP also recommended, as an appropriate alternative for the NPO patient, subcutaneous synthetic ACTH at an initial dose of 25–40 IU (evidence A) (49), with repeat doses as clinically indicated (for either ACTH or intravenous steroid regimens). There was no voting by the TFP on specific followup ACTH or an intravenous steroid dosing regimen, given a lack of evidence. In the scenario of the NPO patient with acute gout, there was no consensus on the use of intramuscular ketorolac or intramuscular triamcinolone acetonide monotherapy. Biologic IL-1 inhibition therapy remains an FDA-unapproved modality for NPO patients, without specific past evaluation in this population.

Critical drug therapy adverse event considerations in acute gout. It was not possible to evaluate every permutation of gout treatment and comorbid disease, given the constraints of the project. The treating clinician will need to carefully weigh the complexities of each unique patient. TFP discussions emphasized that potential drug toxicities due to comorbidities and drug–drug interactions are considerable in treatment of acute gout (30,31). Some examples include underlying moderate and severe CKD (NSAIDs, COX-2 inhibitors, colchicine), congestive heart failure (NSAIDs, COX-2 inhibitors), peptic ulcer disease (NSAIDs, COX-2 inhibitors, corticosteroids), anticoagulation or antiplatelet aggregation therapy (NSAIDs), diabetes mellitus (corticosteroids), ongoing infection or high risk of infection (corticosteroids), and hepatic disease (NSAIDs, COX-2 inhibitors, colchicine) (30,31).

Complementary therapies for acute gout attack. The TFP recommended topical ice application to be an appropriate adjunctive measure to 1 or more pharmacologic therapies for acute gouty arthritis (evidence B) (50). The TFP voted, as inappropriate, the use of a variety of oral complementary agents for the treatment of an acute attack (cherry juice or extract, salicylate-rich willow bark extract, ginger, flaxseed, charcoal, strawberries, black currant, burdock, sour cream, olive oil, horsetail, pears, or celery root).

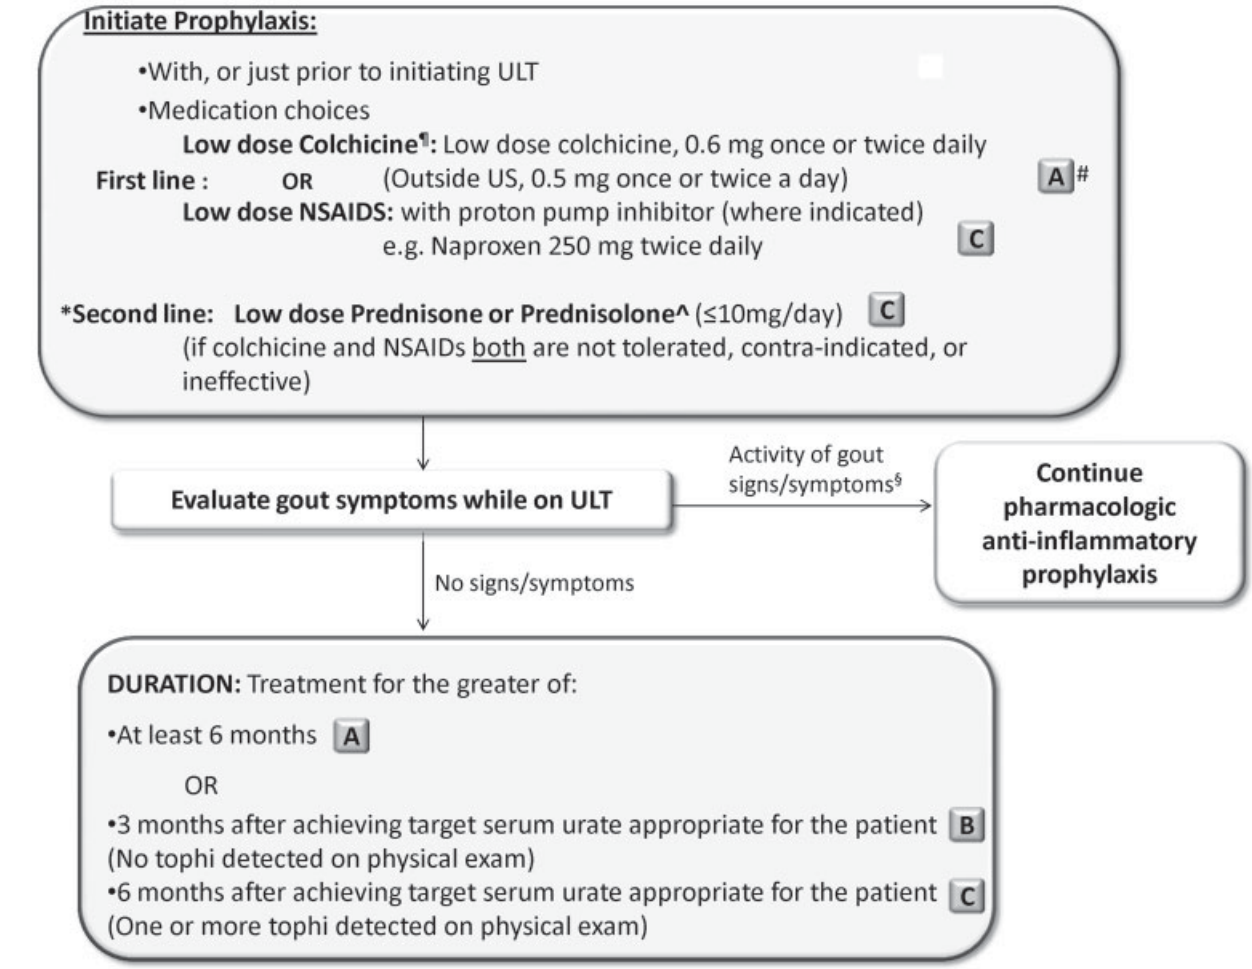
Recommendations for pharmacologic antiinflammatory prophylaxis of attacks of acute gout

The TFP recommended pharmacologic antiinflammatory prophylaxis for all case scenarios of gout where ULT was initiated, given high gout attack rate frequencies in early ULT (evidence A) (51–54) (Figure 5). For gout attack prophylaxis, the TFP recommended, as a first-line option, use of oral colchicine (evidence A) (54,55). The TFP also recommended, as a first-line option (with a lower evidence grade than for colchicine), the use of low-dose NSAIDs (such as naproxen 250 mg orally twice a day), with proton-pump inhibitor therapy or other effective suppression therapy for peptic ulcer disease and its complications, where indicated (evidence C) (54).

In their evaluation of colchicine evidence in gout attack prophylaxis, the TFP specifically recommended low-dose colchicine (0.5 mg or 0.6 mg orally once or twice a day, with dosing further adjusted downward for moderate to severe renal function impairment and potential drug–drug interactions) (30) as appropriate for gout attack prophylaxis. The TFP did not vote on specific quantitative renal function impairment–adjusted dosing of oral colchicine. Since a pharmacokinetic analysis suggesting colchicine dose should be decreased by 50% below a creatinine clearance of 50 ml/minute is unpublished in peer-review form (41), specific quantitative colchicine dose adjustment in CKD is the decision of the treating clinician.

The TFP, in discussion without a specific vote, recognized the evidence that colchicine and low-dose NSAID prophylaxis fail to prevent all gout attacks in patient populations after initiation of ULT (51–54). As an alternative gout attack prophylaxis strategy in patients with intolerance or contraindication or refractoriness to both colchicine and NSAIDs, the TFP recommended use of low-dosage prednisone or prednisolone (defined here as $\leq$10 mg/day) (evidence C). Nevertheless, concerns were raised in discussion among the TFP and by the other authors regarding particularly sparse evidence for efficacy of this low-dose strategy. Given the known risks of prolonged use of corticosteroids, the authors urge clinicians to be particularly attentive in reevaluating the risk/benefit ratio of continued corticosteroid prophylaxis as the risk of acute gout attack decreases with time in conjunction with effective ULT. The TFP voted the use of high daily doses (i.e., $>$10 mg daily) of prednisone or prednisolone for gout attack prophylaxis to be as inappropriate in most case scenarios, and there was a lack of TFP consensus for more severe forms of chronic tophaceous gouty arthropathy. Last, there was a lack of TFP consensus on the risk/benefit ratio for off-label use of biologic IL-1 inhibition (evidence A) (56,57) for antiinflammatory gout attack prophylaxis in patients who previously failed or had intolerance or contraindications to low doses of colchicine, NSAIDs, and prednisone or prednisolone for gout attack prophylaxis.

Duration of antiinflammatory prophylaxis of acute gout attacks. The TFP recommended to continue pharmacologic gout attack prophylaxis if there is any clinical evidence of continuing gout disease activity (such as 1 or



Initiate Prophylaxis:
•With, or just prior to initiating ULT
•Medication choices
Low dose Colchicine¶: Low dose colchicine, 0.6 mg once or twice daily
First line : OR (Outside US, 0.5 mg once or twice a day) A#
Low dose NSAIDS: with proton pump inhibitor (where indicated)
e.g. Naproxen 250 mg twice daily C
*Second line: Low dose Prednisone or Prednisolone^ (≤10mg/day) C
(if colchicine and NSAIDs both are not tolerated, contra-indicated, or ineffective)
Evaluate gout symptoms while on ULT
Activity of gout signs/symptoms§
Continue pharmacologic anti-inflammatory prophylaxis
No signs/symptoms
DURATION: Treatment for the greater of:
•At least 6 months A
OR
•3 months after achieving target serum urate appropriate for the patient B
(No tophi detected on physical exam)
•6 months after achieving target serum urate appropriate for the patient C
(One or more tophi detected on physical exam)

^Without specific task force panel (TFP) vote, the TFP advised that this measure requires particular, continued attention to risk-benefit ratio

§ Examples include: acute gouty arthritis in the past 3 months, presence of palpable tophus or tophi, chronic tophaceous gouty arthropathy (with chronic synovitis) in the past 3 months

**Lack of consensus: Prednisone/prednisolone at doses above 10 mg/day.*

¶ The TFP did not specifically address case scenarios involving renal impairment adjusted colchicine dosing for gout attack prophylaxis

Evidence Grades for Recommendations:
Level A: Supported by multiple (ie, more than one) randomized clinical trials or meta-analyses
Level B: Derived from a single randomized trial, or nonrandomized studies.
Level C: Consensus opinion of experts, case studies, or standard-of-care.

Figure 5. Pharmacologic antiinflammatory prophylaxis of gout attacks and its relationship to pharmacologic urate-lowering therapy (ULT). The figure provides an algorithm for use of antiinflammatory prophylaxis agents to prevent acute gout attacks. The schematic highlights specific recommendations by the TFP on decision making on the initiation, options, and duration of prophylaxis relative to pharmacologic ULT therapy, relative to achievement of the treatment objectives of ULT. NSAIDs = nonsteroidal antiinflammatory drugs.

more tophi detected on physical examination, recent acute gout attacks, or chronic gouty arthritis), and/or the serum urate target has not yet been achieved (1). Specifically, the TFP voted to continue the prophylaxis for the greater of: 1) 6 months' duration (evidence A) (51,53,54), 2) 3 months after achieving the target serum urate level for the patient without tophi detected on physical examination (evidence B), or 3) 6 months after achieving the target serum urate

level, where there has been resolution of tophi previously detected on physical examination (evidence C) (Figure 5).

Discussion

Acute attacks of gout have a detrimental impact on the quality of life of the patient due to pain and dysfunction of affected joints, and acute gout can have a substantial economic and societal impact (58–60). Following a systematic review of the literature and use of a formal group assessment process, we provide the first ACR guidelines for the therapy and antiinflammatory prophylaxis of acute gout attacks.

The TFP recommended multiple modalities (NSAIDs, corticosteroids by different routes, and oral colchicine) as appropriate initial therapeutic options for acute gout attacks. The TFP was informed in part by recent direct comparison studies suggesting approximate equivalency of oral systemic corticosteroids with NSAIDs (28,43). Essentially, the TFP concluded, without a specific vote, that selection of treatment choice is that of the prescribing clinician, and to be based upon factors including patient preference, the patient's previous response to pharmacologic therapies, associated comorbidities and, in the unique case of colchicine, the time since onset of the acute gout attack. The dosing adjustments and relative and absolute contraindications for NSAIDs and colchicine due to associated comorbidities (such as renal and hepatic impairment) and drug interactions were not addressed in these guidelines. There is published literature addressing these issues (30,31) such as quality indicators for safe use of NSAIDs (61–63), including ACR quality indicators for treatment of gout (64).

The TFP recommended a novel set of strict limitations on colchicine doses for acute gout, starting with no more than 1.8 mg over 1 hour in the first 12-hour period of treatment (evidence B) (26), a paradigm shift from widespread prior use of this drug in clinical practice (10,12), but in accordance with FDA guidance. Prior EULAR and BSR recommendations on colchicine dosing for acute gout (10,12) and colchicine low-dose regimen pharmacokinetics (26) informed the TFP recommendation of low-dose colchicine (at a maximum of 0.6 mg twice daily) as a continuation option for an acute gout attack, if started at least 12 hours following the initial low-dose regimen.

For patients with polyarticular joint involvement and severe presentations of gout in 1 or 2 large joints, the TFP recommended, as appropriate, certain first-line combination therapy approaches. Although there is a lack of published randomized controlled trial data to support these recommendations, a large survey of rheumatologists in the US has shown that combination therapy for acute gout is often employed (65).

With respect to antiinflammatory prophylaxis of acute gout attacks, low-dose colchicine or low-dose NSAIDs were recommended as acceptable first-line options by the TFP, with a higher evidence level for colchicine. The use of low-dose colchicine or an NSAID in gout attack prophylaxis is also recommended by EULAR (10). To date, in small clinical trials, low-dose daily oral colchicine was effective in preventing acute gout attacks (3,55), with supportive post hoc analyses in ULT trials (54). The efficacy of low-dose NSAIDs for gout attack prophylaxis also was described in the febuxostat clinical trial program (54); however, prophylaxis was not the primary focus of the trials. Importantly, recent clinical trials of ULT agents have shown substantial rates of acute gout attacks in the first 6 months after the initiation of ULT, even when prophylaxis with colchicine 0.6 mg daily or low-dose NSAID therapy is administered (51–54). It is noteworthy that the TFP recommended prednisone or prednisolone ≤10 mg daily as a second-line option for acute gout prophylaxis, with the caveat that there is a lack of published robust data for the use of low-dose oral prednisone for gout prophylaxis. More investigation is needed to improve management for this clinical problem. Assessment of modulation of cardiovascular event risks by colchicine prophylaxis or by NSAIDs (66) in patients with gout would be particularly informative.

Limitations of the recommendations presented in this article include that only ~30% were based on level A evidence, with approximately half based on level C evidence; this indicates the need for more studies in the aspects of gout management considered here. The process used here was limited by the current trial designs for assessment of acute gout therapies and prophylaxis of antiinflammatory pharmacologic agents in gout. For acute gout studies, most studies were on NSAIDs and involved an active comparator and noninferiority trial design. However, the majority of these studies failed to provide a noninferiority margin, which needs to be defined a priori to assess the validity of these trials. Although the majority of studies assessed pain as the primary outcome for the acute gout trials, there is a lack of a single uniform measure that precludes meta-analysis. Furthermore, there is a lack of consensus on what time period after initiation of therapy constitutes a primary response, since trials ranged from a few hours to 10 days. With the exception of recent analyses of biologic IL-1 inhibitors (56,57), there was a lack of robust clinical trials of gout attack prophylaxis using antiinflammatory pharmacologic agents. Also, the primary measure in these trials is the recurrence of self-reported acute gout attacks, an outcome that has not been validated using Outcome Measures in Rheumatology criteria (67). Efforts are underway to precisely define acute gout attack in gout clinical trials (68). Last, the RAND/UCLA methodology did not address important societal and patient preference issues on treatment costs and cost-effectiveness comparisons between medication choices for acute gout and pharmacologic prophylaxis of acute gout attacks. This is already a pressing question with respect to use of agents, including colchicine and COX-2 selective inhibitors, and would be expected to emerge as a larger issue if biologic IL-1 inhibitors, in late-stage clinical development after phase III studies at the time this was written, obtain regulatory approval for acute gout treatment and prophylaxis.

In summary, these guidelines, the first from the ACR for the management and antiinflammatory prophylaxis of acute attacks of gouty arthritis, have been developed to provide recommendations to clinicians treating patients with gout. The ACR plans to update these guidelines to capture future treatments or advances in the

management and prophylaxis of acute gout, and as the risk/benefit ratios of emerging therapies are further investigated.

Addendum. Therapies that were approved after the original literature review, or diet and lifestyle measures studied after the original literature review, are not included in these recommendations.

ACKNOWLEDGMENTS

We thank Ms Amy Miller and Ms Regina Parker of the ACR for administrative support and guidance. Drs. Jennifer Grossman (UCLA), Michael Weinblatt (Brigham and Women's Hospital, Harvard Medical School), Ken Saag (University of Alabama, Birmingham), and Ted Ganiats (University of California, San Diego) provided valuable guidance on the objectives and process. Rikke Ogawa (UCLA) provided greatly appreciated service as a medical research librarian.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Dr. Terkeltaub had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide guidance for particular patterns of practice and not to dictate the care of a particular patient. The ACR considers adherence to the recommendations within this guideline to be voluntary, with the ultimate determination regarding their application to be made by the physician in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed and endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. ACR recommendations are not intended to dictate payment or insurance decisions, and drug formularies or other third-party analyses that cite ACR guidelines should state this. These recommendations cannot adequately convey all uncertainties and nuances of patient care.

The American College of Rheumatology is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To provide guidance for the management of gout, including indications for and optimal use of urate-lowering therapy (ULT), treatment of gout flares, and lifestyle and other medication recommendations.

Methods. Fifty-seven population, intervention, comparator, and outcomes questions were developed, followed by a systematic literature review, including network meta-analyses with ratings of the available evidence according to the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology, and patient input. A group consensus process was used to compose the final recommendations and grade their strength as strong or conditional.

Results. Forty-two recommendations (including 16 strong recommendations) were generated. Strong recommendations included initiation of ULT for all patients with tophaceous gout, radiographic damage due to gout, or frequent gout flares; allopurinol as the preferred first-line ULT, including for those with moderate-to-severe chronic kidney disease (CKD; stage ≥3); using a low starting dose of allopurinol (≤100 mg/day, and lower in CKD) or febuxostat (≤40 mg/day); and a treat-to-target management strategy with ULT dose titration guided by serial serum urate (SU) measurements, with an SU target of <6 mg/dl. When initiating ULT, concomitant antiinflammatory prophylaxis therapy for a duration of at least 3–6 months was strongly recommended. For management of gout flares, colchicine, nonsteroidal antiinflammatory drugs, or glucocorticoids (oral, intraarticular, or intramuscular) were strongly recommended.

Conclusion. Using GRADE methodology and informed by a consensus process based on evidence from the current literature and patient preferences, this guideline provides direction for clinicians and patients making decisions on the management of gout.

INTRODUCTION

Gout is the most common form of inflammatory arthritis, affecting ~9.2 million adults (3.9%) in the US (1). While the etiology of gout is well-understood and there are effective and inexpensive medications to treat gout, gaps in quality of care persist (2–4). The 2012 American College of Rheumatology (ACR) Guidelines for the Management of Gout (5,6) and other international specialty society guidelines recommend treat-to-target strategies with use of urate-lowering therapy (ULT) (7–10). Despite these recommendations, over the past 2 decades there has been no increase in ULT utilization. Adherence to ULT remains poor (2,11) and is the lowest adherence among treatments for 7 common chronic medical conditions (12). Complicating the efforts to improve adherence is the fact that the prior 2012 ACR Guidelines for the Management of Gout have been criticized due to low quality of evidence supporting treat-to-target recommendations (13,14). Since the 2012 ACR Guidelines for the Management of Gout were published, several clinical trials have been conducted that provide additional evidence regarding the management of gout, leading the ACR Guidelines Subcommittee to determine that new guidelines were warranted.

METHODS

This guideline follows the ACR guideline development process (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines) using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology to rate the certainty of evidence and develop recommendations (15–17), with an emphasis on developing actionable guidelines. ACR policy guided the management of conflicts of interest and disclosures (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines/Gout). A full description of the methods is presented in Supplementary Appendix 1 (available on the *Arthritis Care & Research* web site at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract).

Briefly, the Core Team, Expert Panel, and Voting Panel (consisting of rheumatologists, a general internist, a nephrologist, a physician assistant, and a patient representative) generated 57 population, intervention, comparator, and outcomes (PICO) questions to address the following: indications for ULT (5 questions), approaches to initiating ULT (7 questions), ongoing ULT management (18 questions), gout flares (10 questions), and lifestyle and other medication strategies in patients with gout (9 questions) and in individuals with asymptomatic hyperuricemia (8 questions). PICO questions were posted on the ACR web site for public comment (October 30–November 30, 2018) (for a list of team and panel members, see Supplementary Appendix 2, available on the *Arthritis Care & Research* web site at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract). An in-person Patient Panel of 8 male patients with gout, moderated by one of the voting panel members (JAS), reviewed the evidence report (along with a summary and interpretation by the moderator) and provided patient perspectives and preferences.

The Core Team prespecified outcomes as critical or important for each PICO question for the systematic literature review. Outcomes varied across PICO topic (for details, see Supplementary Appendix 3, at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract). Gout flare and serum urate (SU) concentration (and tophus for PICO question 1) were specified as critical outcomes for all PICO questions specific to ULT. Pain was identified as critical for PICO questions specific

Submitted for publication December 10, 2019; accepted in revised form February 28, 2020.

to gout flare. Gout flare was specified as the only critical outcome for management of lifestyle factors. All other outcomes were specified as important. Without standardized definitions for gout flare as an outcome (18), flare definitions varied by duration of follow-up in the various studies. Based on Patient Panel input, we specified that longer-term outcomes (e.g., 24 months) would be critical, while shorter durations (e.g., ≤12 months) were considered important; it was recognized that very short time points (e.g., <6 months) may reflect the expected flares during ULT initiation.

We conducted systematic literature reviews (including 2 network meta-analyses [NMAs]) to address each PICO question (for search strategies and study selection process, see Supplementary Appendices 4 and 5, respectively, at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract). The first NMA evaluated the impact of starting ULT versus no ULT and the relative impact of the various ULT agents (for details, see Supplementary Appendix 6, available at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract). The second NMA evaluated antiinflammatory agents in gout flare management (for details, see Supplementary Appendix 7, available at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract). To accomplish this second NMA, we grouped similar agents into nodes (e.g., acetic acid derivatives, profens, cyclooxygenase 2 agents, glucocorticoids, and interleukin-1 [IL-1] inhibitors).

The lowest level of evidence for the outcomes deemed critical to patients determined the certainty of evidence for each PICO question (15). For PICO questions specific to ULT, and on the basis of input from 1) the Patient Panel; 2) prior focus group work citing the importance of SU, gout flare, and tophi to patients (19); and 3) prior guidance from the GRADE working group (20), we made the following decisions. Where there was moderate or high certainty of evidence demonstrating improvement in any 1 of these 3 outcomes, we deemed this sufficient evidence to support a strong recommendation. The certainty of evidence from the other 2 outcomes was then designated as important but not critical to support the recommendation. The certainty of the evidence for each recommendation is presented in Tables 1–8, and the certainty of evidence for each outcome within each PICO question is in the full evidence report (see Supplementary Appendix 8, available on the *Arthritis Care & Research* web site at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract).

Additionally, we report results using the more conservative rating of the evidence using the lowest level of evidence for any of the critical outcomes. Applying these more conservative rules, the summary certainty of evidence decreased (in comparison to the reported results) for some of the ULT recommendation statements, which would result in a lower strength of recommendation for 2 recommendations (PICO question 2: ULT indication for patients with erosions, and PICO question 27: switching to pegloticase for ULT failure). The details are available in the evidence report (Supplementary Appendix 8). Medication costs (not part of the systematic literature review), reported as average wholesale pricing as sourced from Lexicomp on August 23, 2019, were provided to the Voting Panel, as cost of treatment was included as part of the evaluation of risks and benefits of treatment medications (see Supplementary Appendix 9, available on the *Arthritis Care & Research* web site at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract).

PICO questions were drafted into recommendation statements and were sent to the Voting Panel with the evidence report prior to round 1 voting. At a face-to-face meeting, the Voting Panel again reviewed draft recommendations, a summary of the voting results from round 1, the evidence report, and a summary of Patient Panel statements (1 patient from the Patient Panel [JES] and the Patient Panel moderator [JAS] attended the Voting Panel and were available to answer questions about the Patient Panel statements). To become a recommendation (for or against) in this guideline, at least 70% consensus of the Voting Panel was required.

The strength of each recommendation was rated as *strong* or *conditional. Strong* recommendations reflect decisions supported by moderate or high certainty of evidence where the benefits consistently outweigh the risks, and, with only rare exceptions, an informed patient and his or her provider would be expected to reach the same decision. *Conditional* recommendations reflect scenarios for which the benefits and risks may be more closely balanced and/or only low certainty of evidence or no data are available.

Recommendations in this guideline apply to patients with gout, except for a single recommendation regarding the use of ULT in individuals with asymptomatic hyperuricemia, which is defined as an SU concentration of ≥6.8 mg/dl with no prior gout flares or subcutaneous tophi. Patients with evidence of monosodium urate monohydrate (MSU) deposition on advanced imaging may still be considered asymptomatic if they have not had a prior gout flare or subcutaneous tophi.

These guidelines do not directly address the impact of gout or hyperuricemia on other comorbidities, such as cardiovascular disease (CVD), hypertension, urolithiasis, or chronic kidney disease (CKD). As we developed these guidelines for use by providers practicing in the US, we considered pharmacologic therapies available in the US, with select exceptions. Although lesinurad was withdrawn from the US market by the manufacturer during the course of guideline development, it remains Food and Drug Administration (FDA) approved, and we therefore considered the data in relation to relevant PICO questions. To facilitate the 2 NMAs, we also considered medications not available in the US to permit comparisons with other available medications in the network analysis.

RESULTS/RECOMMENDATIONS

Indications for pharmacologic ULT

Initiating ULT is strongly recommended for gout patients with any of the following: ≥1 subcutaneous tophi; evidence of radiographic damage (any modality) attributable to gout; OR frequent gout flares, with frequent being defined as ≥2 annually.

From the ULT NMA (see Supplementary Appendix 6, available at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract) and randomized clinical trials (RCTs) of pegloticase (21–23) and lesinurad (24), there was high certainty of evidence regarding the efficacy of ULT in reducing flare frequency (23–26), tophi (21,23), and SU concentrations (23–26). While many Patient Panel participants reported that they were initially hesitant to start ULT, after experiencing improved control of inflammatory symptoms and tophi, they became strong advocates for its earlier institution (for all indications for pharmacologic ULT, see Table 1 and Supplementary Figure 1, available at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract).

Initiating ULT is conditionally recommended for patients who have previously experienced >1 flare but have infrequent flares (<2/year).

For patients with less frequent flares and no tophi, the potential clinical benefit of ULT would be lower than the ULT benefit for patients with more burdensome gout. In a single study (moderate certainty of evidence), patients with ≤2 previous flares (and no more than 1 gout flare in the preceding year) randomized to receive febuxostat (versus placebo) were less likely to experience a subsequent flare (30% versus 41%; $P < 0.05$) (27).

Specific characteristics for patients with infrequent flares (e.g., SU concentration >9 mg/dl, CKD, CVD) that might influence the risk-benefit assessment were considered, but due to insufficient data for these subgroups, the Voting Panel did not find that these conditions warranted stronger ULT recommendations specific to these subgroups.

Initiating ULT is conditionally recommended *against* in patients with gout experiencing their first gout flare.

However, initiating ULT is conditionally recommended for patients with comorbid moderate-to-severe CKD (stage ≥3), SU concentration >9 mg/dl, or urolithiasis.

While conditionally recommending *against* ULT initiation following the first gout flare in a patient with "uncomplicated" gout, the Voting Panel considered Patient Panel input and recognized that there may be patients who would prefer (or benefit from) ULT, underscoring the need for shared decision-making. As noted above, data from the RCT of patients with ≤2 previous flares (and no more than 1 gout flare in the preceding year) supported the benefit of ULT for reduction of SU concentration and gout flare risk (27). For patients with moderate-to-severe CKD (e.g., stage ≥3), there is a higher likelihood of gout progression and development of clinical tophi (28–30). Furthermore, treatment options for gout flare are limited in this population, and there may be added benefit of using ULT to prevent progression of renal disease (31). Similarly, patients with markedly elevated SU concentrations (>9 mg/dl) are more likely to experience gout progression (26,32). For patients with a history of urolithiasis, allopurinol and febuxostat provide benefit, as both medications lower 24-hour urinary uric acid excretion more than placebo (33). Among patients with calcium oxalate stones and hyperuricosuria, allopurinol (300 mg/day) is superior to placebo in reducing the 3-year incidence of stone-related events (34).

Table 1. Indications for pharmacologic urate-lowering therapy (ULT)*

Recommendation	PICO question	Certainty of evidence
For patients with 1 or more subcutaneous tophi, we strongly recommend initiating ULT over no ULT.	1	High
For patients with radiographic damage (any modality) attributable to gout, we strongly recommend initiating ULT over no ULT.	2	Moderate
For patients with frequent gout flares (≥2/year), we strongly recommend initiating ULT over no ULT.	3	High
For patients who have previously experienced >1 flare but have infrequent flares (<2/year), we conditionally recommend initiating ULT over no ULT.	4	Moderate
For patients experiencing their first flare, we conditionally recommend *against* initiating ULT over no ULT, with the following exceptions.	5	Moderate
For patients experiencing their first flare and CKD stage ≥3, SU >9 mg/dl, or urolithiasis, we conditionally recommend initiating ULT.	5	Very low
For patients with asymptomatic hyperuricemia (SU >6.8 mg/dl with no prior gout flares or subcutaneous tophi), we conditionally recommend *against* initiating any pharmacologic ULT (allopurinol, febuxostat, probenecid) over initiation of pharmacologic ULT.	57	High†

Strongly recommend | Conditionally recommend | Strongly recommend against | Conditionally recommend against

* PICO = population, intervention, comparator, outcomes; CKD = chronic kidney disease; SU = serum urate.
† There is randomized clinical trial data to support the benefit that ULT lowers the proportion of patients who develop incident gout. However, based on the attributable risk, 24 patients would need to be treated for 3 years to prevent a single (incident) gout flare leading to the recommendation against initiating ULT in this patient group.

Initiating ULT is conditionally recommended *against* in patients with asymptomatic hyperuricemia.

For patients with asymptomatic hyperuricemia, RCTs (designed to study CVD outcomes) demonstrated significant reduction in incident gout flares over 3 years. However, the development of incident gout was low for both ULT and placebo arms (<1% versus 5%) (35,36). In other words, 24 patients would need to be treated with ULT for 3 years to prevent a single (incident) gout flare. From observational studies, among patients with asymptomatic hyperuricemia with SU concentrations of >9 mg/dl, only 20% went on to develop gout within 5 years (32). The Voting Panel felt that, on average, for the majority of patients with asymptomatic hyperuricemia (including those with comorbid CKD, CVD, urolithiasis, or hypertension), the benefits of ULT would not outweigh potential treatment costs or risks for the large number of patients unlikely to progress to gout. This is also the case for patients with asymptomatic hyperuricemia with MSU crystal deposition as noted on imaging tests such as ultrasound or dual-energy computed tomography.

Recommendations for choice of initial ULT for patients with gout

Treatment with allopurinol as the preferred first-line agent, over all other ULTs, is strongly recommended for all patients, including those with moderate-to-severe CKD (stage ≥3).

The Voting Panel strongly recommended allopurinol as the preferred first-line agent given its efficacy when dosed appropriately (often required doses >300 mg/day [37] up to the maximum FDA-approved dose of 800 mg/day [38]), tolerability, safety, and lower cost. Using a lower starting dose mitigates safety issues specific to allopurinol hypersensitivity syndrome (AHS) (39,40). The Voting Panel indicated that an optimal trial of oral medication would be appropriate prior to pegloticase due to cost differences and potential adverse effects of the latter medication (for recommendations for choice of initial ULT, see Table 2 and Supplementary Figure 2, available at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract).

The choice of either allopurinol or febuxostat over probenecid is strongly recommended for patients with moderate-to-severe CKD (stage ≥3).

The choice of pegloticase as a first-line therapy is strongly recommended *against*.

Starting treatment with low-dose allopurinol (≤100 mg/day and lower in patients with CKD [stage ≥3]) and febuxostat (≤40 mg/day) with subsequent dose titration over starting at a higher dose is strongly recommended.

Starting treatment with low-dose probenecid (500 mg once to twice daily) with subsequent dose titration over starting at a higher dose is conditionally recommended.

A lower starting dose of any ULT reduces the risk of flare associated with initiation (41). The Patient Panel voiced a strong preference for safer ULT prescribing regimens through lower starting doses with subsequent dose escalation, even if such regimens required more blood draws and provider visits, over alternate regimens (e.g., starting with higher doses) that might incur more risk. Even lower initial allopurinol doses (e.g., ≤50 mg/day)

Table 2. Recommendations for choice of initial urate-lowering therapy (ULT) in patients with gout*

Recommendation	PICO question	Certainty of evidence
For patients starting any ULT, we strongly recommend allopurinol over all other ULT as the preferred first-line agent for all patients, including in those with CKD stage ≥3.	10	Moderate
We strongly recommend a xanthine oxidase inhibitor over probenecid for those with CKD stage ≥3.		
For allopurinol and febuxostat, we strongly recommend starting at a low dose with subsequent dose titration to target over starting at a higher dose (e.g., ≤100 mg/day [and lower in patients with CKD] for allopurinol or ≤40 mg/day for febuxostat).	7	Moderate
For probenecid, we conditionally recommend starting at a low dose (500 mg once or twice daily) with dose titration over starting at a higher dose.		
We strongly recommend initiating concomitant antiinflammatory prophylaxis therapy (e.g., colchicine, NSAIDs, prednisone/prednisolone) over no antiinflammatory prophylaxis. The choice of specific antiinflammatory prophylaxis should be based upon patient factors.	9	Moderate
We strongly recommend continuing prophylaxis for 3–6 months rather than <3 months, with ongoing evaluation and continued prophylaxis as needed if the patient continues to experience flares.	9	Moderate
When the decision is made that ULT is indicated while the patient is experiencing a gout flare, we conditionally recommend starting ULT during the gout flare over starting ULT after the gout flare has resolved.	6	Moderate
We strongly recommend *against* pegloticase as first-line therapy.	10	Moderate†

Strongly recommend | Conditionally recommend | Strongly recommend against | Conditionally recommend against

* PICO = population, intervention, comparator, outcomes; CKD = chronic kidney disease; NSAIDs = nonsteroidal antiinflammatory drugs.
† Moderate evidence is in support of the efficacy of pegloticase, but due to cost, safety concerns, and favorable benefit-to-harm ratios of other untried treatment options, the recommendation is *against* using pegloticase as first-line agent.

should be considered in patients with CKD. While higher starting doses and CKD are associated with risk of AHS (39), patients with CKD may still require dose titration above 300 mg/day to achieve the SU target (42,43). A population pharmacokinetic–pharmacodynamics study showed that larger body size and diuretic use indicated the need for higher allopurinol doses to achieve greater urate reduction. Worse renal function only had a modest negative impact on urate reduction (44). Other studies have demonstrated that allopurinol dose escalation can be done safely in this population (40,45).

Administering concomitant antiinflammatory prophylaxis therapy (e.g., colchicine, nonsteroidal antiinflammatory drugs [NSAIDs], prednisone/prednisolone) over no antiinflammatory prophylaxis therapy is strongly recommended.

Based on 8 RCTs (41,46–52) and 2 observational studies (53,54), there is moderate certainty of evidence to support the strong recommendations to use antiinflammatory prophylaxis therapy when initiating ULT. Continuation of prophylaxis for at least 3–6 months after ULT initiation was recommended because shorter durations were associated with flares upon cessation of prophylaxis (55,56). After cessation, monitoring for flare activity and continuation of antiinflammatory treatment as needed if the patient continues to experience flares was recommended.

Continuing concomitant antiinflammatory prophylaxis therapy for 3–6 months over <3 months, with ongoing evaluation and continued prophylaxis as needed if the patient continues to experience gout flares, is strongly recommended.

Timing of ULT initiation

When the decision is made that ULT is indicated while the patient is experiencing a gout flare, starting ULT during the gout flare over starting ULT after the gout flare has resolved is conditionally recommended.

Starting ULT during a flare has conceptual benefits, including the time efficiency offered by initiating therapy during the concurrent flare visit rather than risking the patient not returning for ULT initiation. Furthermore, input from the Patient Panel emphasized that patients are likely to be highly motivated to take ULT due to the symptoms related to the current flare. However, concerns about starting ULT during a flare include potential extension or worsening of a flare, as well as the possibility of information overload for patients, which may lead to conflating flare management and long-term ULT. Two small RCTs (57,58) and an observational study (59) support the hypothesis that starting ULT during a flare does not significantly extend flare duration or severity. Input from the Patient Panel, citing their own ability to simultaneously process information related to flare treatment and ULT initiation together, along with their preference to start on a treatment path sooner to prevent future flares, influenced the final recommendation. As with all conditional recommendations, there may be patient factors or preferences that would reasonably support the alternative of delaying ULT initiation until the flare has resolved.

A treat-to-target management strategy that includes ULT dose titration and subsequent dosing guided by serial SU measurements to achieve a target SU, over a fixed-dose ULT strategy, is strongly recommended for all patients receiving ULT.

Achieving and maintaining an SU target of <6 mg/dl over the use of no target is strongly recommended for all patients receiving ULT.

We recommend using a treat-to-target management strategy to optimize patient outcomes by achieving and maintaining an SU target of <6 mg/dl rather than using a fixed-dose strategy (Table 3 and Supplementary Figure 2, available at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract). There is moderate- and high-quality evidence supporting these 2 recommendations. In an RCT from the UK (43), patients randomized to a nurse-led, treat-to-target protocol demonstrated greater ULT adherence, lower SU concentrations, reduction in tophi, and a lower proportion of frequent (≥2) gout flares at 24 months, compared with patients randomized to general practitioner–led usual care (an approach more often characterized by a fixed-dose strategy when ULT is administered). Two separate pharmacist-led interventions in the US, both incorporating treat-to-target strategies, were superior to usual care in terms of treatment adherence, SU outcomes, and higher allopurinol dosing (60,61). Additional studies provide support for ULT dose escalation to achieve target SU levels, including dose titration of allopurinol in patients with CKD (40,43). While a specific dose titration schedule is left to provider and patient to individualize based on patient comorbidities and preferences, ULT titration should occur over a reasonable time frame (e.g., weeks to months, not years) to prevent "treatment inertia" (62). In contrast to the 2012 ACR Guidelines for the Management of Gout, due to lack of supporting evidence for additional specific thresholds, we do not define further thresholds for patients warranting more intensive ULT.

Delivery of an augmented protocol of ULT dose management by nonphysician providers to optimize the treat-to-target strategy that includes patient education, shared decision-making, and treat-to-target protocol is conditionally recommended for all patients receiving ULT.

Based on recent nurse- (43) and pharmacist-led (60,61) interventions, the Voting Panel supported the benefit of an augmented delivery-of-care using patient education and shared decision-making through implementation of a treat-to-target protocol over

Table 3. Recommendations for all patients taking urate-lowering therapy (ULT)*

Recommendation	PICO question	Certainty of evidence
For all patients taking ULT, we strongly recommend a treat-to-target strategy of ULT dose management that includes dose titration and subsequent dosing guided by serial SU values to achieve an SU target over a fixed, standard-dose ULT strategy.	13	Moderate
For all patients taking ULT, we strongly recommend continuing ULT to achieve and maintain an SU target of <6 mg/dl over no target.	14	High
For all patients taking ULT, we conditionally recommend delivery of an augmented protocol of ULT dose management by nonphysician providers to optimize the treat-to-target strategy that includes patient education, shared decision-making, and treat-to-target protocol.	8	Moderate
We conditionally recommend continuing ULT indefinitely over stopping ULT.	19	Very low

Strongly recommend | Conditionally recommend | Strongly recommend against | Conditionally recommend against

* PICO = population, intervention, comparator, outcomes; SU = serum urate.

usual care. However, the panel recognized that these resources may not be available in all health care settings, and that the key is for the treating provider (who could be the treating physician) to educate the patient and implement a treat-to-target protocol.

Duration of ULT

Continuing ULT indefinitely over stopping ULT is conditionally recommended.

For patients in clinical remission taking ULT (e.g., no flares for ≥1 year and no tophi [63]), the Voting Panel considered ULT cessation or tapering. In a single case series where ULT was withheld in patients in clinical remission with years of well-controlled SU concentrations prior to cessation, only 13% of patients (27 of 211) whose SU concentration remained at <7 mg/dl while not receiving ULT had no flares during a 5-year follow-up period. Furthermore, patients with higher SU concentrations after withholding therapy had more frequent flares with greater likelihood of flares associated with higher SU levels (37). The Patient Panel voiced concerns about a return or worsening of gout symptoms, tophi, or joint damage with ULT cessation. If therapy is well-tolerated and not burdensome, the Patient Panel expressed a preference to continue treatment.

Recommendations for patients receiving ULT medications

Allopurinol

Testing for the HLA–B*5801 allele prior to starting allopurinol is conditionally recommended for patients of Southeast Asian descent (e.g., Han Chinese, Korean, Thai) and for African American patients, over not testing for the HLA–B*5801 allele.

Universal testing for the HLA–B*5801 allele prior to starting allopurinol is conditionally recommended *against* in patients of other ethnic or racial background over testing for the HLA–B*5801 allele.

As noted above, starting allopurinol in daily doses of ≤100 mg (and lower doses in patients with CKD) is strongly recommended over starting at a higher dose.

The HLA–B*5801 allele is associated with a markedly elevated risk for AHS (64,65). The prevalence of HLA–B*5801 is highest among persons of Han Chinese, Korean, and Thai

Table 4. Recommendations for patients taking specific urate-lowering therapy (ULT) medications*

Recommendation	PICO question	Certainty of evidence
Allopurinol		
We conditionally recommend testing HLA–B*5801 prior to starting allopurinol for patients of Southeast Asian descent (e.g., Han Chinese, Korean, Thai) and African American patients, who have a higher prevalence of HLA–B*5801.	12	Very low
We conditionally recommend *against* HLA–B*5801 testing in all others.		
For patients with a prior allergic response to allopurinol who cannot be treated with other oral ULT, we conditionally recommend using allopurinol desensitization.	23	Very low
Febuxostat		
For patients with gout taking febuxostat with a history of CVD or a new CV event, we conditionally recommend switching to an alternative ULT agent if available and consistent with other recommendations in this guideline.	22	Moderate
Uricosurics		
For patients considered for, or taking uricosuric treatment, prior to starting any uricosuric treatment, we conditionally recommend *against* checking urinary uric acid over checking urinary uric acid.	28	Very low
For patients taking uricosuric treatment, we conditionally recommend *against* alkalinizing urine.	29	Very low

Strongly recommend | Conditionally recommend | Strongly recommend against | Conditionally recommend against

* PICO = population, intervention, comparator, outcomes; CVD = cardiovascular disease.

descent (7.4%) (66), lower among African Americans (3.8%), and even lower among whites and Hispanics (0.7% each) (66). Testing for this allele among Asians and African American patients was reported to be cost-effective (incremental cost-effectiveness ratios <$109,000 per quality-adjusted life years) (67). Asian and African American patients taking allopurinol both have a 3-fold increased risk of AHS compared with white patients taking allopurinol (68) (for recommendations for ULT medications, see Table 4 and Supplementary Figure 3, available at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract).

Allopurinol desensitization is conditionally recommended for patients with a prior allergic response to allopurinol who cannot be treated with other oral ULT agents.

The level of evidence supporting this recommendation was very low (69,70). The Voting Panel recognized that desensitization protocols (69,70) are not commonly used, with the majority of currently practicing rheumatologists having limited experience in these protocols.

Febuxostat

Switching to an alternative oral ULT agent, if available and consistent with other recommendations in this guideline, is conditionally recommended for patients taking febuxostat with a history of CVD or a new CVD-related event.

At the Voting Panel meeting, there was much discussion about the data, Patient Panel input, and interest to provide recommendations consistent with the FDA black box warning for febuxostat (71). The Voting Panel considered data from the CARES RCT (72) and 2 observational studies (73,74). In the FDA-mandated CARES trial of febuxostat versus allopurinol (72), there was no difference between the 2 arms in the primary composite CVD end point. Febuxostat, however, was associated with a higher risk of CVD-related death and all-cause mortality (driven by CVD deaths) compared with allopurinol, but there was no association with the other 3 secondary CVD outcomes (nonfatal myocardial infarction, nonfatal stroke, or urgent revascularization for unstable angina). Interpretation of these results is complicated by a high dropout rate with a majority of deaths occurring after ULT discontinuation (72). Moreover, the lack of an untreated control group means the absolute CVD risk related to febuxostat is unknown. A large observational study (recruitment not selected for CVD) did not show an increased risk of CVD or all-cause mortality associated with febuxostat initiation compared with allopurinol using methods to address confounding by indication (73). Another study using a managed care database demonstrated lower risk of any major CVD event among febuxostat initiators than allopurinol initiators, though confounding by indication may not have been adequately addressed (74). The Patient Panel representative stated members would be willing to accept "some" incremental CVD risk as long as the treatment adequately controlled their gout. Thus, as for many such decisions with conditional recommendations, providers and patients should engage in shared decision-making when considering febuxostat for patients at high risk for CVD.

Uricosurics

Checking urinary uric acid is conditionally recommend *against* for patients considered for or receiving uricosuric treatment.

Alkalinizing the urine is conditionally recommended *against* for patients receiving uricosuric treatment.

A single observational study demonstrated that higher levels of 24-hour urinary uric acid and higher levels of undissociated urinary uric acid were associated with urolithiasis (75). However, the Voting Panel indicated that the challenges with 24-hour urine collection or nomogram-based testing, which can both be affected by diet, negate the utility of such testing in light of a very low level of evidence.

We found no evidence to support a recommendation of checking urinary uric acid level for patients receiving uricosuric treatment or for alkalinizing the urine. The Voting Panel supported standard best practice that patients with known renal calculi or moderate-to-severe CKD (stage $\geq$3) should not be treated with uricosurics. For patients who are treated with uricosurics, patients should receive counseling about adequate hydration, but they need not be prescribed alkalinizing agents given the lack of evidence for efficacy.

As use of uricosurics remains infrequent, we did not formally vote on indications for uricosuric medications. However, we concur with the 2012 ACR Guidelines for the Management of Gout that add-on therapy to partially responsive xanthine oxidase inhibitor (XOI) treatment can result in improved SU control (24,25,76).

When to consider changing ULT strategy

Switching to a second XOI over adding a uricosuric agent is conditionally recommended for patients taking their first XOI, who have persistently high SU concentrations (>6 mg/dl) despite maximum-tolerated or FDA-indicated XOI dose, and who have continued frequent gout flares (>2 flares/year) OR who have nonresolving subcutaneous tophi.

Several lesinurad studies demonstrated the benefit of adding a uricosuric medication to XOI treatment (25,76). However, we found no studies directly addressing the choice in the above

PICO question, resulting in the conditional recommendation to switch to a second XOI after the first XOI failure (for recommendations for consideration of changing ULT strategy, see Table 5 and Supplementary Figure 2, available at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract).

Switching to pegloticase over continuing current ULT is strongly recommended for patients with gout for whom XOI treatment, uricosurics, and other interventions have failed to achieve the SU target, and who continue to have frequent gout flares (≥2 flares/year) OR who have nonresolving subcutaneous tophi.

Switching to pegloticase over continuing current ULT is strongly recommended *against* for patients with gout for whom XOI treatment, uricosurics, and other interventions have failed to achieve the SU target, but who have infrequent gout flares (<2 flares/year) AND no tophi.

In clinical trials, patients with 3 or more self-reported gout flares during the previous 18 months, ≥1 tophi, and gouty arthropathy, defined clinically or radiographically as joint damage due to gout, were randomly assigned to pegloticase treatment. Patients additionally had contraindication to treatment with allopurinol or history of treatment failure to normalize uric acid despite ≥3 months of treatment with the maximum medically appropriate allopurinol dose (determined by the treating physician). For these patients with frequent gout flares or nonresolving subcutaneous tophi, clinical trials demonstrated improved SU concentrations, low frequency of flares (77), reduction in tophi (21), and improved quality of life (22) among those receiving pegloticase. However, these outcomes come with high costs, twice-monthly infusions, and the potential for serious allergic reactions. For patients with infrequent gout flares and no tophi, we would expect a similar benefit in SU reduction. For patients with only infrequent flares, the magnitude of benefit would be substantially smaller than for patients with frequent flares, and there would be no benefit in reduction of tophi when no tophi are present. The harms and costs of administering pegloticase would likely be similar in patients with mild versus severe disease, resulting in limited benefit and appreciable harm along with very high costs, leading the panel to conclude that the costs and harms clearly outweigh the benefits. This conclusion, along with strong Patient Panel statements about not wanting to receive twice-monthly infusions to prevent infrequent gout flares, resulted in the strong recommendation *against* using pegloticase for patients with mild disease.

The above scenarios represent extremes of gout clinical severity resulting in strong "for" and "against" recommendations. The Voting Panel considered intermediary scenarios, but given the potential variability, the panel opted to simply defer to provider judgment balanced with patient preferences, regarding the optimal treatment strategy for individuals not described above. To clarify, as outlined above, there is a strong recommendation to follow a treat-to-target management strategy for all patients receiving ULT. However, the recommendation for treat-to-target strategy is not absolute and not meant to be pursued at "any cost." Even strong recommendations require sound clinical judgment to balance the potential clinical benefits and harms (including costs) of medical decisions (78).

Gout flare management

Using colchicine, NSAIDs, or glucocorticoids (oral, intraarticular, or intramuscular) as appropriate first-line therapy for gout flares over IL-1 inhibitors or adrenocorticotropic hormone (ACTH) is strongly recommended for patients experiencing a gout flare.

Given similar efficacy and a lower risk of adverse effects, low-dose colchicine over high-dose colchicine is strongly recommended when colchicine is the chosen agent.

Table 5. When to consider switching to a new urate-lowering therapy (ULT) strategy*

Recommendation	PICO question	Certainty of evidence
For patients with gout taking their first XOI monotherapy at maximum-tolerated or FDA-indicated dose who are not at SU target and/or have continued frequent gout flares or nonresolving subcutaneous tophi, we conditionally recommend switching the first XOI to an alternate XOI agent over adding a uricosuric agent.	24	Very low
For patients with gout where XOI, uricosurics, and other interventions have failed to achieve SU target and who have frequent gout flares or nonresolving subcutaneous tophi, we strongly recommend switching to pegloticase over continuing current ULT.†	27	Moderate
For patients with gout for whom XOI, uricosurics, and other interventions have failed to achieve serum urate target and who have infrequent gout flares (<2 flares/year) and no tophi, we strongly recommend *against* switching to pegloticase over continuing current ULT.‡	27	Moderate

Strongly recommend | Conditionally recommend | Strongly recommend against | Conditionally recommend against

* PICO = population, intervention, comparator, outcomes; XOI = xanthine oxidase inhibitor; FDA = Food and Drug Administration.
† There is moderate certainty of evidence about the efficacy of the benefits, harms, and high certainty about the costs of pegloticase. For patients with high disease activity, the magnitude of potential benefits outweighs the harms and costs of the drug.
‡ For patients with minimal disease activity, the smaller potential benefits do not outweigh the harms and costs of the drug.

Using topical ice as an adjuvant treatment over no adjuvant treatment is conditionally recommended for patients experiencing a gout flare.

Using an IL-1 inhibitor over no therapy (beyond supportive/analgesic treatment) is conditionally recommended for patients experiencing a gout flare for whom the above antiinflammatory therapies are either ineffective, poorly tolerated, or contraindicated.

Treatment with glucocorticoids (intramuscular, intravenous, or intraarticular) over IL-1 inhibitors or ACTH is strongly recommended for patients who are unable to take oral medications.

The Voting Panel's recommendation of colchicine, NSAIDs, or glucocorticoids as preferred first-line therapies was based on substantial trial data demonstrating efficacy, relative low cost (versus IL-1 inhibitors and ACTH), and tolerability of these agents in flare management, particularly when administered early after symptom onset. Appropriate dosing and duration should be guided by the severity of the flare. For colchicine specifically, the FDA-approved dosing should be followed (1.2 mg immediately followed by 0.6 mg an hour later, with ongoing antiinflammatory therapy until the flare resolves). Based on similar efficacy between agents demonstrated in the NMA (79–88), the Voting Panel did not further prioritize between the first-line agents, noting that treatment selection should be driven by patient factors (e.g., comorbidity, access, past experience) as part of shared decision-making. Likewise, parenteral glucocorticoids were favored over alternative agents when oral dosing is not possible. In patients experiencing an inadequate response to an initial agent, the Voting Panel cited insufficient evidence to make specific recommendations regarding subsequent antiinflammatory agents to use. If a patient is unable to tolerate or has contraindications to any of the other conventional alternatives, the Voting Panel conditionally recommended the use of IL-1 inhibitors (84,88–90), recognizing concerns over patient access due to cost. Noting limited supporting data (91), the Voting Panel recommended the use of topical ice as an adjuvant therapy for flares.

Underscoring the importance of optimal flare management, the Patient Panel emphasized its preference for early intervention given the challenges of engaging a provider in timely manner, including an at-home "medication-in-pocket" strategy for patients who are able to identify the early signs of flare onset. In the absence of "rapid" access to an effective oral medication, the Patient Panel also indicated its preference for an injectable therapy in appropriate circumstances to achieve pain relief as quickly as possible (for all recommendations for gout flare managment, see Table 6 and Supplementary Figure 4, available at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract).

Management of lifestyle factors

Limiting alcohol intake is conditionally recommended for patients with gout, regardless of disease activity.

Limiting purine intake is conditionally recommended for patients with gout, regardless of disease activity.

Limiting high-fructose corn syrup intake is conditionally recommended for patients with gout, regardless of disease activity.

Using a weight loss program (no specific program endorsed) is conditionally recommended for those patients with gout who are overweight/obese, regardless of disease activity.

Table 6. Gout flare management*

Recommendation	PICO question	Certainty of evidence
For patients experiencing a gout flare, we strongly recommend using oral colchicine, NSAIDs, or glucocorticoids (oral, intraarticular, or intramuscular) as appropriate first-line therapy for gout flares over IL-1 inhibitors or ACTH (the choice of colchicine, NSAIDs, or glucocorticoids should be made based on patient factors and preferences). When colchicine is the chosen agent, we strongly recommend low-dose colchicine over high-dose colchicine given its similar efficacy and fewer adverse effects.	32	High†
For patients experiencing a gout flare for whom other antiinflammatory therapies are poorly tolerated or contraindicated, we conditionally recommend using IL-1 inhibition over no therapy (beyond supportive/analgesic treatment).	33	Moderate
For patients who may receive NPO, we strongly recommend glucocorticoids (intramuscular, intravenous, or intraarticular) over IL-1 inhibitors or ACTH.	32	High†
For patients experiencing a gout flare, we conditionally recommend using topical ice as an adjuvant treatment over no adjuvant treatment.	31	Low

Strongly recommend | Conditionally recommend | Strongly recommend against | Conditionally recommend against

* PICO = population, intervention, comparator, outcomes; NSAIDs = nonsteroidal antiinflammatory drugs; IL-1 = interleukin-1; ACTH = adrenocorticotropic hormone; NPO = nothing by mouth (nulla per os).
† High quality of evidence from network meta-analyses supporting canakinumab, which has superior mean pain score reduction and mean day-2 joint tenderness reduction. However, the Voting Panel raised concern that the comparator was weak (triamcinolone 40 mg) and that cost issues significantly favor other agents.

Adding vitamin C supplementation is conditionally recommended *against* for patients with gout, regardless of disease activity.

The Voting Panel discussed data demonstrating the important genetic contributions to the development and severity of hyperuricemia and gout (92,93) and informally recommended that providers be mindful when soliciting information regarding the dietary habits of patients and ensure that discussions regarding dietary recommendations are not misinterpreted as "patient-blaming," as patients frequently feel stigmatized when discussing gout with their providers (94). Dietary modifications likely yield only small changes in SU concentration, but dietary factors may serve as triggers for flares, and patients frequently seek advice on dietary management (for recommendations for management of lifestyle factors, see Table 7 and Supplementary Figure 5, available at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract).

Alcohol. SU levels among patients who limited or abstained from alcohol were 1.6 mg/dl lower compared with patients who did not do so (95,96). Results from a recent diet and genetics meta-analysis that was noted above (92) demonstrated that the impact of diet or individual food items on SU concentration was small. As an example, a unit of beer raised SU concentrations by 0.16 mg/dl. The effects of a healthy diet, Mediterranean diet, or Dietary Approaches to Stop Hypertension (DASH) diet were even smaller (92).

In a case-crossover study, consuming >1–2 alcoholic beverage servings in the prior 24 hours was associated with a 40% higher risk of gout flare than periods without alcohol consumption, with a dose-response relationship (97). A small cohort study demonstrated that despite receiving ULT, heavy drinkers (≥30 units of alcohol/week) were more likely to continue having gout flares compared with those who do did not drink heavily (95).

Low purine diet. From the same case-crossover study noted above, there was a dose-response relationship between increasing purine intake and risk of gout flare (98). However, a small RCT (n = 29, with all participants receiving ULT with SU at target at the start of trial) using an educational intervention focused on low purine intake did not demonstrate lower SU concentrations compared with usual diet, despite significant improvements in patient dietary knowledge (99).

High-fructose corn syrup. The ingestion of 1 gm of fructose/kg of body weight increases SU concentration by 1–2 mg/dl within 2 hours of ingestion (100). In the National Health and Nutrition Examination Survey, artificially sweetened carbonated beverage consumption was associated with higher SU levels (101). In the Nurses' Health Study, greater consumption of high-fructose corn syrup was associated with higher risk of incident gout (102). However, there were no data focused on patients with existing gout.

Weight loss. The Voting Panel considered the impact of weight loss and specific dietary programs (including the DASH diet [103]). Due to small sample sizes, studies of patients without gout (or not defined), and risk of bias assessments, the certainty of the evidence was rated as very low for both SU and flares. Several studies and a systematic literature review (104) addressed weight loss approaches either directly (96,105) or indirectly (e.g., bariatric surgery [106,107], or dietary advice [108]). In a small cohort (n = 11) of obese patients, a mean weight loss of 5 kg resulted in a mean SU lowering of 1.1 mg/dl (96). In a large cohort study, obesity was associated with a higher risk of incident gout, but not recurrent gout flares (105). However, changes in body mass index (BMI) over time were associated with the risk of recurrent gout flare. An increase in BMI of >5% was associated with 60% higher odds of recurrent flare, and a decrease in BMI of >5% was associated with 40% lower odds of recurrent flare compared with those without weight change (–3.5% ≤ BMI ≤ 3.5%) (105). A small study of 12 patients undergoing bariatric surgery (mean 34.3 kg weight loss over 12 months) demonstrated a mean SU reduction of 2.0 mg/dl (106). Likewise, gout patients losing weight through bariatric surgery or diet experienced reduced flare frequency (108), although patients undergoing bariatric surgery may actually have

Table 7. Management of lifestyle factors*

Recommendation	PICO question	Certainty of evidence
For patients with gout, regardless of disease activity, we conditionally recommend limiting alcohol intake.	41	Low
For patients with gout, regardless of disease activity, we conditionally recommend limiting purine intake.	42	Low
For patients with gout, regardless of disease activity, we conditionally recommend limiting high-fructose corn syrup.	43	Very low
For overweight/obese patients with gout, regardless of disease activity, we conditionally recommend weight loss.	46	Very low
For patients with gout, regardless of disease activity, we conditionally recommend *against* adding vitamin C supplementation.	48	Low

Strongly recommend | Conditionally recommend | Strongly recommend against | Conditionally recommend against

* PICO = population, intervention, comparator, outcomes.

a transient increase in flares risk during the first postoperative month (106).

Other dietary recommendations. The Voting Panel reviewed the data for cherries/cherry extract and dairy protein. The certainty of evidence drawn mainly from observational studies was low or very low, precluding specific recommendations on these topics. The Voting Panel reached consensus that data on vitamin C were insufficient to support continued recommendation for its use in patients with gout. Two small RCTs (n = 29 and n = 40) showed clinically insignificant changes in SU concentrations for patients with gout taking vitamin C (99,109).

Management of concurrent medications

Switching hydrochlorothiazide to an alternate antihypertensive when feasible is conditionally recommended for patients with gout, regardless of disease activity.

Choosing losartan preferentially as an antihypertensive agent when feasible is conditionally recommended for patients with gout, regardless of disease activity.

Stopping low-dose aspirin (for patients taking this medication for appropriate indications) is conditionally recommended *against* for patients with gout, regardless of disease activity.

Adding or switching cholesterol-lowering agents to fenofibrate is conditionally recommended *against* for patients with gout, regardless of disease activity.

Medications noted above are known to have effects on SU concentrations (110). The Voting Panel made recommendations specific to hydrochlorothiazide and losartan (111) in clinical scenarios where such changes are feasible. Switching, stopping, or adding a medication should only be considered when the potential SU concentration/gout benefits exceed the potential risks or harms of the medication change.

Recognizing that there are few practical alternatives to low-dose aspirin, the Voting Panel specifically recommended against its cessation as a means of SU reduction when a patient is taking it for an appropriate indication. Likewise, the Voting Panel specifically recommended against adding or switching cholesterol-lowering agents (e.g., statins, bile acid sequestrants, nicotinic acid agents, etc.) to fenofibrate despite its urate-lowering effects (112), as the risks, including side effects of the medication, were felt to outweigh potential benefits. Although likely to render only modest urate-lowering effects, switching from an angiotensin-converting enzyme inhibitor to losartan carries a risk that seems to be sufficiently low in most patients to merit this change when feasible (for all recommendations for management of concurrent medications, see Table 8 and Supplementary Figure 5, available at http://onlinelibrary.wiley.com/doi/10.1002/acr.24180/abstract).

DISCUSSION

This guideline reinforces many of the prior 2012 ACR Guidelines for the Management of Gout recommendations with updated literature and GRADE methodology, including incorporation of patient preferences and consideration of costs. The Voting Panel endorsed 42 recommendations overall, including 16 strong recommendations focused on ULT management (indications [n = 3], initiation [n = 6], titration and treat-to-target approach [n = 2], approaches following ULT failure [n = 2]), and flare management (n = 3).

Data from more recent RCTs comparing treat-to-target protocols versus usual care (43,61) provide the basis for the strong recommendation to use a treat-to-target strategy with ULT that includes a plan to achieve and maintain an SU target of <6 mg/dl to optimize patient outcomes. Findings from the evidence report resonated with the Patient Panel who concurred that their own SU levels correlated with related symptoms and changes in tophi. Patients on this panel articulated that SU assessments reinforced the importance of treatment adherence.

These guidelines reinforce the strategy of starting with low-dose ULT and titrating up to achieve the SU target. This strategy mitigates the risk of treatment-related adverse effects (e.g., hypersensitivity) as well as flare risk accompanying ULT initiation (39,41). Lacking data on optimal titration regimens, the Voting Panel indicated that titration should be individualized, based on available provider resources (e.g., staff for augmented delivery of care), patient preferences, the timing of ambulatory encounters,

Table 8. Management of concurrent medications*

Recommendation	PICO question	Certainty of evidence
For patients with gout, regardless of disease activity, we conditionally recommend switching hydrochlorothiazide to an alternate antihypertensive when feasible.	47	Very low
We conditionally recommend choosing losartan preferentially as an antihypertensive when feasible.	47	Very low
We conditionally recommend *against* stopping low-dose aspirin (in those who are taking this medication for appropriate indications).	47	Very low
We conditionally recommend *against* adding or switching to fenofibrate.	47	Very low

Strongly recommend | Conditionally recommend | Strongly recommend against | Conditionally recommend against

* PICO = population, intervention, comparator, outcomes.

and antiinflammatory treatments. As described above, ULT titration should occur over weeks to months, not years. The 2012 ACR Guidelines for the Management of Gout recommended titration every 2–5 weeks (5). As noted in the ACR Clinical Quality Measures for Gout, SU concentrations should be checked after each dose titration (113). To limit the risk of ULT-related flares, these guidelines reinforce prior recommendations to use concurrent antiinflammatory prophylaxis for 3–6 months' duration, a shorter duration than advocated for in prior recommendations, but one that should be extended in the setting of frequent ongoing flares.

Breaking from prior ACR and European League Against Rheumatism (EULAR) guidelines, this guideline does not specify SU thresholds beyond <6 mg/dl for patient subsets with more severe disease (e.g., those with tophi). This guideline is not intended to contradict or dispute prior recommendations. There is ample evidence that lower SU levels hasten the resolution of tophi (23,114) and are associated with less frequent gout flares (26,114), suggesting that lower SU thresholds may be preferable for patients with more burdensome gout. However, in contrast to a treatment strategy using an SU target of <6 mg/dl as studied in clinical trials (43), there are no trial data to support lower specific thresholds for such patients.

In contrast to the 2012 ACR Guidelines for the Management of Gout (which did not consider treatment costs), this document firmly places allopurinol as the preferred first-line ULT for all patients, including those with CKD, due to the respective cost of each medication and potential CVD safety concerns that have recently emerged with febuxostat (72).

Under GRADE methodology, recommendations in these guidelines are supported by higher quality studies than the 2012 ACR Guidelines for the Management of Gout. This resulted in a more focused, less proscriptive document. Where certainty of data is less than moderate or high, conditional recommendations made herein are meant to highlight those decisions that would benefit from a shared patient-provider decision-making process. This would include areas such as diet, lifestyle, or concomitant medications that might affect SU levels, and for which the Patient Panel requested guidance. The Voting Panel aimed to provide guidance without implying any "patient-blaming" for the manifestations of gout given its strong genetic determinants.

Indications for ULT are expanded from the 2012 ACR Guidelines for the Management of Gout, but consistent with the 2016 update of the EULAR gout recommendations (10), to include individuals with evidence of radiographic damage attributable to gout (using any modality, regardless of subcutaneous tophi or flare frequency). This strong recommendation recognizes the various ways in which gout may present, and that joint damage is reflective of an active biologic process. Also added were conditional recommendations (which would warrant provider-patient shared medical decision-making discussion) for ULT use in patients with either infrequent flares (<2 flares/year) or a first flare with marked hyperuricemia (SU >9 mg/dl). Similar to the 2012 ACR Guidelines for the Management of Gout, the Voting Panel advocated a "medication-in-pocket" strategy for gout flare management, which the Patient Panel reinforced as a preferred approach.

This updated guideline effort also identifies several areas that inform a research agenda for gout management. While data support an active treat-to-target strategy, a question remains as to what may be the optimal SU threshold for patients with more severe disease, in addition to questions about threshold values in specific populations of gout patients. Gout has differential impact on patients by sex, race, or by presence of other comorbidities. This guideline is limited in commenting on specific groups of gout patients, as more studies of specific patient cohorts are needed in order to make differential recommendations. Additional studies are needed to determine the safety of prolonged and profound treatment-related hypouricemia (e.g., SU ≤3 mg/dl), an important knowledge gap given that epidemiologic studies have suggested an inverse association of SU concentration with select neurodegenerative disorders (115). While there are associations between SU and other comorbid conditions such as hypertension, CVD, and CKD (116), the benefit (or risk) of ULT in the absence of gout has yet to be established (117).

Gout has been characterized as a "curable disease" (118). As data continue to emerge supporting best practices in management, implementation of these recommendations will ideally lead to improved quality of care for patients with gout.

ACKNOWLEDGMENTS

We thank Theodore R. Fields, MD, FACP, Angelo L. Gaffo, MD, and Kenneth G. Saag, MD, for serving on the Expert Panel. We thank Jasvinder A. Singh for leading the Patient Panel meeting, as well as the patients who participated in this meeting: Lynn Brown, Jr., Douglas P. Davis, Larry Davis, Dextral L. Ely, Adam Paul Germek, Willie Earl Henton, James Edward Sims, and James Trucks. We thank N. Lawrence Edwards, MD, for his review of the manuscript. We thank Amit Aakash Shah, MD, MPH, for his assistance with the literature review. We thank the ACR staff, including Regina Parker for assistance in organizing the face-to-face meeting and coordinating the administrative aspects of the project, and Robin Lane for assistance in manuscript preparation. We thank Janet Joyce for help in developing the literature search strategy and performing the initial literature search, and Janet Waters for performing the update searches.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be submitted for publication. Dr. Neogi had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Scope and purpose

Background

The rationale behind this update of the 2016 British Society for Rheumatology (BSR) guidelines on prescribing antirheumatic drugs in pregnancy and breastfeeding [1, 2] was described in detail in the guideline scope [3]. In brief, despite the existence of additional evidence-based guidelines on prescribing/managing rheumatic disease in pregnancy [4–7], the information contained within them requires continual review to include emerging information on the safety of new and existing drugs in pregnancy.

Chronic disease adversely affects pregnancy. Data from Mothers and Babies: Reducing Risk through Audits and Confidential Enquiries across the UK (MBRRACE-UK) reports regularly from a national programme of work conducting surveillance and investigating the causes of maternal deaths, stillbirths and infant deaths [8]. Data from 2017–19 found that 8.8 women per 100 000 died during pregnancy or up to six weeks after childbirth or the end of pregnancy, and most women who died had multiple health problems or other vulnerabilities [8]. In all decisions regarding medication choices and changes, it is important to consider the potential for deterioration in the mother's wellbeing through side effects or reduced disease control (and its adverse impact on the baby). As such, the potential benefit to the foetus from any drug changes in the mother must be balanced against the possible risks to the foetus from loss of disease control in the mother [9].

Need for guideline

There has been an appreciable increase in the number of published pregnancy exposures to biologic DMARDs (bDMARDs), and two of these drugs are now licensed for use in pregnancy. In addition, therapeutic advances in management of various inflammatory rheumatic diseases (IRDs) have led to an expansion of bDMARDs and biosimilars with different modes of action, as well as a new class of targeted synthetic DMARDs (tsDMARDs).

The continuing expansion of existing and novel DMARDs means that uncertainty remains around the use of many of these drugs in pregnancy. This uncertainty may still lead to withdrawal of treatment from pregnant women unnecessarily [10]. Discontinuation of treatment in preparation for or during early pregnancy can increase the risk of disease activity and flares during pregnancy, and are reported following discontinuation of biologics in patients with IRDs [11]. The compatibility of various immunosuppressive and disease-modifying medications relevant to rheumatic disease will be covered in this update. This updated information will provide advice for healthcare professionals and patients, to ensure more confident prescribing in these scenarios, and will highlight any medications that should be stopped and/or avoided in the reproductive age group unless highly effective contraception is used, in line with guidance issued by the Medicines and Healthcare Products Regulatory Agency (MHRA) and the Faculty of Sexual and Reproductive Healthcare [12, 13].

Objectives of guideline

To update the previous BSR guidelines on prescribing in pregnancy in rheumatic disease of the following drug categories: antimalarials; corticosteroids; conventional synthetic (cs)DMARDs and immunosuppressive therapies; bDMARDs; and tsDMARDs. The full list of medications is shown in Supplementary Data S1, available at *Rheumatology* online. This revised guideline was produced by systematically reviewing all evidence published since the previous guideline, to answer specific questions in relation to each drug, as follows: Should it be stopped pre-conception? Is it compatible with pregnancy? Is it compatible with breastmilk exposure? Where possible, recommendations are made regarding compatibility with paternal exposure.

Target audience

The primary audience consists of health professionals in the UK directly involved in managing patients with rheumatic disease who are (or are planning to become) pregnant and/or breastfeeding, men with rheumatic disease who are planning to conceive, and patients with rheumatic disease who have unintentionally conceived while taking these medications. This audience includes rheumatologists, rheumatology nurses/allied health professionals, rheumatology speciality trainees and pharmacists, as well as the patients themselves. The guideline will also be useful to obstetricians, obstetric physicians, midwives, renal physicians, dermatologists, gastroenterologists, respiratory physicians and general practitioners who prescribe these medications in pregnancy.

This guideline uses the terms 'woman', 'maternal' or 'mother' throughout. These should be taken to include people who do not identify as women but are pregnant or have given birth [14]. Where the term 'breastfeeding' is used in this guideline it also refers to infant breastmilk exposure via other methods (e.g. expressed breastmilk, administered via a bottle).

The areas the guideline does not cover

This guideline does not cover the management of infertility or the indications for these drugs in specific rheumatic diseases in pregnancy. Other drug categories (pain management; NSAIDs and low dose aspirin; anticoagulants; bisphosphonates; anti-hypertensives; and pulmonary vasodilators) are considered in the BSR guideline on prescribing drugs in pregnancy and breastfeeding: comorbidity medications used in rheumatology practice (https://doi.org/10.1093/rheumatology/keac552). All recommendations in this guideline were formulated by the working group on the basis of published evidence at the time of the systematic literature search, and do not necessarily refer to licensing information or Summary of Product Characteristics for individual medications.

Stakeholder involvement

This guideline was commissioned by the BSR Standards, Guidelines and Audit Working Group. A Guideline Working group (GWG) was created, consisting of a chair (I.G.), alongside representatives from relevant stakeholders shown in Supplementary Table S1, available at *Rheumatology* online. In accordance with BSR policy, all members of the GWG made declarations of interest, available on the BSR website.

Involvement and affiliations of stakeholder groups involved in guideline development

The GWG consisted of rheumatologists from a range of clinical backgrounds, various allied health professionals, other specialists in women's health, lay members and representatives from the United Kingdom Teratology Information

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

Service (UKTIS). All members of the working group contributed to the process for agreeing key questions, guideline content, recommendations and strength of agreement.

Rigour of development

Statement of scope of literature search and strategy employed

The evidence used to develop these guidelines was compiled from a systematic literature search conducted according to guidelines of Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) [15]. Studies were identified by searching MEDLINE and Embase databases from 1 January 2014 to 31 December 2020 using combinations of the key MESH and free terms: pregnancy; lactation; breastfeeding; paternal exposure; and the name of each drug. The full electronic search strategies for the MEDLINE and Embase databases are shown in Supplementary Data S2, available at *Rheumatology* online. Searches were not limited by disease indication; in addition to IRDs, studies in non-rheumatic diseases, such as psoriasis, inflammatory bowel disease (IBD) and organ transplantation were considered, if relevant. Additional published studies were identified through the Cochrane, LactMed (a National Library of Medicine database on drugs and lactation) and UKTIS databases (weblinks shown in Supplementary Data S2, available at *Rheumatology* online), and checking of reference lists from recently published national and international guidelines and systematic literature reviews. Due to the paucity of data pertaining to the use of non-TNFi biologic drugs and tsDMARDs in pregnancy and breastmilk exposure, relevant pharmaceutical companies were contacted between July and November 2021, and asked for any further available data.

Two independent reviewers screened the titles and abstracts of articles from the searches then reviewed the full texts of relevant studies, selecting articles that met inclusion criteria of: randomized and non-randomized controlled trials; cohort studies; case-control studies; and case series with more than ten participants. For medications with data on fewer than 300 pregnancy exposures, case series with more than five participants were eligible for inclusion. Conference abstracts were eligible for inclusion if they contained sufficient relevant data and there was no corresponding published manuscript. Case reports, and case series with fewer than five participants, were excluded, as were animal studies. Data extraction was performed by two reviewers. Disagreements arising during screening and extraction were resolved by group discussion, with involvement of a third reviewer where necessary.

Statement of methods used to formulate the recommendations (levels of evidence)

The working group met regularly to formalize the search strategy, review evidence, resolve disagreements and, finally, to determine recommendations. This guideline was developed in line with BSR's Guidelines Protocol using Grading of Recommendations, Assessment, Development and Evaluations (GRADE) methodology to determine quality of evidence and strength of recommendation. Accompanying each recommendation in this guideline, in brackets, is the strength of recommendation, quality of evidence and strength of agreement (SOA).

Strength of recommendation

Using GRADE, recommendations were categorized as either strong (denoted by 1) or weak (denoted by 2), according to the balance between benefits and risks. A strong recommendation was made when the benefits clearly outweigh the risks (or vice versa). A weak recommendation denotes that the benefits are more closely balanced with the risk or more uncertain.

Quality of evidence

Using the GRADE approach, the quality of evidence was determined as either high (A), moderate (B) or low/very low (C), reflecting the confidence in the estimates of benefits or harm.

Strength of agreement

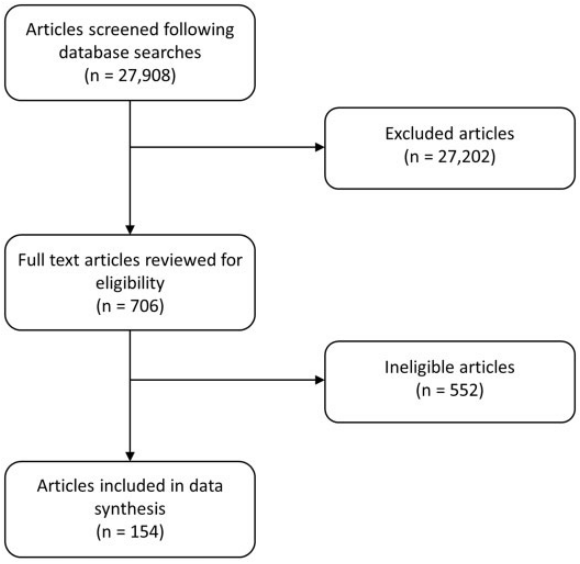
The wording of each recommendation was revised until all members were satisfied that they would score at least 80 on a scale of 1 (no agreement) to 100 (complete agreement). The 20/24 working group members with full voting rights then scored each recommendation on the same scale, and the average was calculated to generate a strength of agreement (SOA) score. Two patient representatives and data analysts expressed concern that they did not have sufficient medical knowledge of all drugs reviewed to score all recommendations; so while they fully agreed with each recommendation, they did not wish to score each one, and did not contribute to the final SOA score.

Statement of any limits of search and when the guideline will be updated

The search was conducted in January 2021. Limits were placed for English language and filters as described above. The guideline will be updated in five years.

The guideline

A flow diagram of study selection is shown in Fig. 1, displaying the initial number of articles screened ($n = 27\,908$), the number of articles selected for full-length review ($n = 706$), and the number included in the final analysis from this



Articles screened following database searches (n = 27,908)
Excluded articles (n = 27,202)
Full text articles reviewed for eligibility (n = 706)
Ineligible articles (n = 552)
Articles included in data synthesis (n = 154)

Figure 1. Flow diagram of studies selected for inclusion

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

updated search ($n = 154$). This information was then merged with the results of the previous guideline's systematic review to give the total exposure data for each drug. The following data were extracted where possible for each medication: number of studies and study type; number of pregnancy exposures; number of live births; pregnancy duration; birth weight; maternal complications; miscarriages; number and type of congenital anomalies (where possible, congenital anomalies described in original publications were classified as major/minor according to European surveillance of congenital anomalies (EUROCAT) definitions [16]); breastmilk exposure; long-term follow-up; and paternal exposure. An overall summary of compatibility of each drug pre-conception, during pregnancy, with breastmilk exposure, and with paternal exposure is shown in Table 1. For each drug, maternal information is summarized in the text and in Tables 2 and 3, while paternal exposures and recommendations are described separately and shown in Table 4. The data synthesis strategy for Tables 2–4 is shown in Supplementary Data S3, available at *Rheumatology* online. Other relevant papers identified in our search that did not meet the inclusion criteria are discussed in the main text.

Generic recommendations on prescribing immunomodulatory drugs and/or corticosteroids in rheumatic disease in pregnancy

i) Pre-conception counselling should be addressed by all healthcare professionals, with referral to professionals with relevant expertise as appropriate, to optimize disease control before pregnancy; with advice on the timing of pregnancy, and drug therapy before, during and after pregnancy, including contraception (GRADE 1A, SOA 99.5%).
ii) If a woman is planning pregnancy, avoid pregnancy-incompatible drugs (GRADE 1A, SOA 100%).
iii) The risks and benefits to the mother and foetus of drug treatment to control maternal disease should be discussed and clearly documented by all healthcare professionals involved in the patient's care (GRADE 1A, SOA 99.5%).
iv) Immunomodulatory drugs that are contraindicated in pregnancy should be switched to a pregnancy-compatible alternative in advance of conception to ensure maintenance of disease control on the new medication (GRADE 1A, SOA 100%).
v) When no pregnancy-compatible drugs are suitable, control of severe/life-threatening maternal disease should take priority over concerns for potential foetal outcomes (GRADE 1B, SOA 99.0%).
vi) All biologic DMARDs may be continued throughout pregnancy if required to control active/severe maternal disease (GRADE 1B, SOA 98.5%).
vii) Immunization schedules in infants after *in-utero* exposure to biologic DMARDs will depend on timing of exposure, bioavailability and persistence of the drug, mechanism of action of the drug, and live vaccines (GRADE 1C, SOA 99.5%).
viii) Where possible, the minimum effective dose of immunomodulatory drug or corticosteroid should be used to maintain maternal disease suppression, and stopping the drug during pregnancy may be considered in women at low risk of disease flare on withdrawal of therapy (GRADE 1B, SOA 100%).
ix) Some drugs may reduce male fertility, but paternal drug exposure in humans has not convincingly been associated with adverse foetal development or pregnancy outcome. Although the evidence is weak, men who take rheumatological medicines should be reassured about the safety of conceiving (GRADE 2C, SOA 98.4%).

Antimalarials

HCQ is the antimalarial drug most used to treat rheumatic disease and has been extensively studied in pregnancy. We identified an additional 23 studies [17–39] that, combined with the previous 23 studies [40–62], reported on ($n = 4701$) pregnancy exposures to HCQ, with very limited information on other antimalarials [17, 39, 63, 64]. Many of these studies were confounded by primarily reporting pregnancy outcomes in patients with SLE treated with other immunosuppressive agents, including MMF and corticosteroids, and use in anti-Ro/La positive patients in the prevention of congenital heart block (CHB). Despite these limitations, there were no appreciable adverse effects of HCQ on pregnancy duration or birth weight in the largest studies. In fact, several studies comparing HCQ-treated and untreated cohorts with rheumatic disease (mostly SLE) either found no significant difference between cohorts [17, 19, 21, 24, 28, 34, 36, 37], or significantly longer pregnancy durations and/or higher birth weight in the HCQ-treated pregnancies [18, 20, 22, 25, 27, 29, 30, 32, 33, 35]. The weighted mean for gestation across 15 studies reporting pregnancy duration in HCQ-exposed *vs* HCQ-unexposed pregnancies was 36.4 weeks and 34.7 weeks, respectively [18–21, 24, 27, 28, 30, 32–34, 36, 37, 43, 49]. The weighted mean for birth weight for HCQ-exposed *vs* HCQ-unexposed pregnancies was 2847 and 2733 g, respectively, in 10 studies reporting these outcomes [18, 20, 21, 27, 29, 33, 34, 36, 37, 43]. A total of 60 first trimester miscarriages were reported from 524 HCQ-exposed pregnancies (11.5%) in 10 studies, compared with 117 first trimester miscarriages in 718 HCQ-unexposed pregnancies (16.3%) [18–22, 27, 28, 30, 32, 33]. No specific pattern of congenital malformations was observed in association with HCQ exposure. No increased risk of adverse foetal outcomes was reported in >3229 chloroquine-exposed pregnancies in four studies [17, 39, 63, 64], including two studies where chloroquine was used as malaria prophylaxis during pregnancy; although, in these two studies, higher rates of maternal adverse events were reported, relative to the comparator (sulfadoxine-pyrimethamine). No information was found on mepacrine.

The findings for HCQ were consistent across all studies apart from a large population-based cohort study comparing HCQ-exposed ($n = 2045$) and HCQ-unexposed ($n = 21\,679$) pregnancies in patients with rheumatic disease, which did not control fully for disease, comorbidity-related pregnancy risk factors, dose of corticosteroids and combination with specific immunosuppressive drugs [23]. This study found a small increase in the risk of congenital malformations associated with first trimester HCQ use, mainly oral clefts, respiratory anomalies and urinary defects, with wide confidence intervals for specific malformations. A statistically significant increase in risk, however, was only found with daily doses of ≥400 mg of HCQ. This study concluded that for most patients with

Table 1. Summary of drug compatibility in pregnancy and breastmilk exposure

	Peri-conception	First trimester	Second/third trimester	Breastfeeding	Paternal exposure
Corticosteroids					
Prednisolone	Yes	Yes	Yes	Yes	Yes
Antimalarials					
Hydroxychloroquine (≤400 mg/day)	Yes	Yes	Yes	Yes	Yes
Conventional synthetic DMARDs					
Methotrexate (≤25 mg/week)	Stop ≥1 month pre-conception	No	No	No	Yes
Sulfasalazine (with folic acid 5 mg/day in first trimester)	Yes	Yes	Yes	Yes[a]	Yes[b]
Leflunomide	No: Cholestyramine washout	No	No	No	Yes
Azathioprine	Yes	Yes	Yes	Yes	Yes
Ciclosporin	Yes	Yes[c]	Yes[c]	Yes	Yes
Tacrolimus	Yes	Yes[c]	Yes[c]	Yes	Yes
Cyclophosphamide	Exceptional circumstances[d]	Exceptional circumstances[d]	Exceptional circumstances[d]	No	No
Mycophenolate mofetil	Stop ≥6 weeks pre-conception	No	No	No	Yes
Intravenous immunoglobulin	Yes	Yes	Yes	Yes	Yes
Anti-TNFα medications					
Infliximab	Yes	Yes	Yes[e]	Yes	Yes
Etanercept	Yes	Yes	Yes[f]	Yes	Yes
Adalimumab	Yes	Yes	Yes[g]	Yes	Yes
Certolizumab	Yes	Yes	Yes	Yes	Yes
Golimumab	Yes	Yes	Yes[g]	Yes	Yes
Other biologic DMARDs					
Rituximab	Consider stopping at conception[h]	Severe disease if no alternatives[h]	Severe disease if no alternatives[i]	Yes[j]	Yes[j]
IL-6 inhibitors	Consider stopping at conception[h]	Severe disease if no alternatives[h]	Severe disease if no alternatives[i]	Yes[j]	Yes[j]
IL-1 inhibitors	Consider stopping at conception[h]	Severe disease if no alternatives[h]	Severe disease if no alternatives[i]	Yes[j]	Yes[j]
Abatacept	Consider stopping at conception[h]	Severe disease if no alternatives[h]	Severe disease if no alternatives[i]	Yes[j]	Yes[j]
Belimumab	Consider stopping at conception[h]	Severe disease if no alternatives[h]	Severe disease if no alternatives[i]	Yes[j]	Yes[j]
IL-17 inhibitors	Consider stopping at conception[h]	Severe disease if no alternatives[h]	Severe disease if no alternatives[i]	Yes[j]	Yes[j]
IL-12/23 inhibitors	Consider stopping at conception[h]	Severe disease if no alternatives[h]	Severe disease if no alternatives[i]	Yes[j]	Yes[j]
Targeted synthetic DMARDs					
JAK-inhibitors	Stop ≥2 weeks pre-conception	No	No	No	Yes[j]

For further information and caveats, see relevant recommendations and main text in the executive summary and full guideline.

[a] In the healthy, full-term infant only.
[b] If conception is delayed by >12months, consider stopping sulfasalazine alongside investigation of other causes of infertility.
[c] Suggested monitoring of maternal blood pressure, renal function, blood glucose and drug levels.
[d] Only in cases of severe (life or organ-threatening) maternal disease.
[e] If low risk of disease flare and stopped by 20 weeks, full-term infant can have a normal vaccination schedule.
[f] If low risk of disease flare and stopped by 32 weeks, full-term infant can have a normal vaccination schedule.
[g] If low risk of disease flare and stopped by 28 weeks, full-term infant can have a normal vaccination schedule.
[h] May be considered to manage severe maternal disease if no other pregnancy-compatible drugs are suitable.
[i] If used in third trimester, avoid live vaccinations in infant vaccination schedule until 6 months of age.
[j] Limited evidence.

Table 2. Summary of maternal exposure to conventional synthetic DMARDs, antimalarials and corticosteroids

Drug	Studies (type and number)	Pregnancy exposures (exposures per trimester)	Foetal losses/ total pregnancy outcomes	Pregnancy duration and birth weight	Malformations/total births	Recommendation (GRADE/Strength of agreement)
HCQ	31 ct [17–25, 27, 28, 30–39, 44–53] 1 rct [29] 1 nrt [26] 2 cc [42, 43] 3 cs [54–56] 6 cr [57–62] 2 sr [40, 41]	4701 (1st ≥3075, 2nd/3rd ≥583)	95/936	No significant adverse effect noted	162/3126 Overall, no increase in rate of major malformations attributable to drug	i) HCQ remains the antimalarial of choice in women planning a pregnancy with rheumatic disease in need of treatment, and should be continued during pregnancy at dose of ≤400 mg/day (GRADE 1B, SOA 100%) ii) HCQ is compatible with breastmilk exposure (GRADE 1B, SOA 99.5%)
Pred/MP	3 rct [84–86] 3 cc [43, 87, 88] 22 ct [31, 46, 48, 51–53, 71, 73–81, 89–95] 12 cs [55, 72, 96–105] 16 cr [55, 57, 59–61, 96–117] 1 Cochr [82] 1 sr [83]	2733 (1st ≥995, 2nd/3rd ≥637)	70/518	No significant adverse effect attributable to drug	63/697 No increase in rate of major malformations attributable to drug	i) Prednisolone is compatible with pregnancy and is the preferred corticosteroid in the treatment of maternal rheumatological disease in pregnancy and requires shared care with obstetric teams to monitor maternal blood pressure and blood glucose (GRADE 1B, SOA 100%) ii) Where possible, the dose of prednisolone should be <20 mg/day and tapered to the minimum effective dose to control maternal disease, in conjunction with steroid-sparing drugs compatible with pregnancy (GRADE 1C, SOA 99.5%) iii) Prednisolone is compatible with breastmilk exposure (GRADE 1B, SOA 100%) iv) Methylprednisolone has similar rates of placental transfer to prednisolone and would therefore be expected to be compatible with pregnancy and breastmilk exposure (GRADE 2C, SOA 99%)
MTX	2 cc [172, 181] 8 ct [37, 50, 52, 91, 179, 180, 182, 183] 1 cs [173] 5 cr [174–178]	766 (1st trimester ≥239, 2nd/3rd trimester ≥8)	80/479	Insufficient data; only one study reported birthweight in a cohort of $n = 23$ [37], with two studies reporting pregnancy duration ($n = 43$) [37, 181]	36/265 Individual case reports of MTX embryopathy, but larger studies show limited numbers of cases of foetal malformation	i) MTX at any dose should be avoided in pregnancy and stopped at least one month in advance of planned conception, when it should be switched to another pregnancy-compatible drug to ensure maintenance of maternal disease suppression (GRADE 1A, SOA 98%) ii) In women treated with low-dose (≤25 mg/week) MTX within one month prior to conception, folic acid supplementation (5 mg/day) should be continued up to 12 weeks of pregnancy (GRADE 1B, SOA 99.5%) iii) In unintended pregnancy on low-dose MTX (≤25 mg/week), there is minimal risk to the foetus; the drug should be stopped immediately, folic acid supplementation (5 mg/day) continued, and a careful evaluation of foetal risk with early referral to a foetal medicine department considered (GRADE 1C, SOA 100%) iv) Although only minute amounts of MTX are excreted into breastmilk, MTX cannot be recommended in breastfeeding because of theoretical risks and insufficient data on outcomes (GRADE 2C, SOA 99%)

Table 2. (continued)

Drug	Studies (type and number)	Pregnancy exposures (exposures per trimester)	Foetal losses/ total pregnancy outcomes	Pregnancy duration and birth weight	Malformations/total births	Recommendation (GRADE/Strength of agreement)
SSZ	3 ct [46, 50, 52] 1 cs [55] 2 cr [62, 193]	178 (NR)	NR	No significant adverse effect noted	Rate not specifically quantified in the majority of papers. Overall, no increase in rate of major malformations attributable to drug	i) SSZ is compatible throughout pregnancy, with folic acid 5 mg/day recommended in the periconception period and during the first trimester (GRADE 1B, SOA 100%) ii) SSZ is compatible with breastmilk exposure in healthy, full-term infants (GRADE 1C, SOA 99.5%)
LEF	6 ct [50, 91, 194, 199–201] 4 cr [195–198]	814 (1st ≥156, 2nd/3rd ≥24)	138/811	No significant adverse effect noted	42/525 Overall, no increase in rate of major malformations attributable to drug, but most cases stopped in 1st trimester and received cholestyramine washout	i) LEF may not be a human teratogen but there remains insufficient evidence to support use at the time of conception or during pregnancy (GRADE 1B, SOA 98%) ii) Women on LEF considering pregnancy should stop and undergo a standard cholestyramine washout procedure, and switch to alternative medication compatible with pregnancy (GRADE 1B, SOA 98.8%) iii) If unintended conception occurs on LEF, the drug should be stopped immediately and a standard cholestyramine washout procedure given, with early referral to a foetal medicine department considered (GRADE 1B, SOA 99%) iv) LEF is not recommended while breastfeeding (GRADE 1C, SOA 99.5%)
AZA	5 cc [88, 135, 172, 203, 204] 16 ct [31, 45, 50–52, 78, 90, 92, 93, 95, 205, 206, 212–215] 6 cs [55, 99, 102, 173, 207, 208] 2 cr [61, 107] 1 sr [83]	1757 (1st ≥1254, 2nd/3rd ≥580)	130/642	No significant adverse effect noted	18/487 Overall, no increase in rate of major malformations attributable to drug	i) AZA is compatible throughout pregnancy (GRADE 1B, SOA 100%) ii) AZA is compatible with breastmilk exposure (GRADE 2C, SOA 99.5%)
CsA	4 cc [43, 88, 135, 136] 8 ct [50, 51, 92, 93, 95, 182, 219, 220] 3 cs [54, 101, 165]	401 (1st ≥131, 2nd/3rd ≥136)	9/132	Possible trend towards shorter pregnancy duration [92, 101, 136, 165] and low birth weight [88, 92, 165]	2/26 Data confounded by concomitant AZA/ MMF exposure	i) CsA is compatible throughout pregnancy with monitoring of maternal blood pressure, renal function, blood glucose and drug levels (GRADE 1B, SOA 100%) ii) CsA is compatible with breastmilk exposure (GRADE 2C, SOA 99.7%)
TAC	1 ct [92, 93, 219, 223, 225–231] 1 cs [99] 2 cr [107, 116]	515 (1st ≥302, 2nd/3rd ≥135)	108/451	Insufficient data to confirm lack of a significant adverse effect	12/270 Overall, insufficient data, mainly in organ transplant cohorts	i) TAC is compatible throughout pregnancy with monitoring of maternal blood pressure, renal function, blood glucose and drug levels (GRADE 2B, SOA 100%) ii) TAC is compatible with breastmilk exposure (GRADE 2C, SOA 99.8%)

Table 2. (continued)

Drug	Studies (type and number)	Pregnancy exposures (exposures per trimester)	Foetal losses/ total pregnancy outcomes	Pregnancy duration and birth weight	Malformations/total births	Recommendation (GRADE/Strength of agreement)
CYC	1 cs [102] 4 cr [106, 111, 167, 168] 1 ct [232]	20 (1st ≥6, 2nd/3rd ≥2)	2/16	Insufficient data	0/13 Few data, from individual case reports or case series, available	i) CYC is a known teratogen and gonadotoxic, and therefore should only be considered in pregnancy in cases of severe life/organ-threatening maternal disease when there is appreciable risk of maternal and foetal morbidity and mortality without this therapy (GRADE 1B, SOA 99.5%) ii) CYC is not recommended while breastfeeding (GRADE 2C, SOA 100%)
MMF	7 ct [92, 95, 215, 242–245] 3 cs [99, 208, 235] 12 cr [57, 60, 113, 114, 116, 236–241]	804 (1st ≥796, 2nd/3rd ≥320)	371/753	Evidence of reduced pregnancy duration and birth weight	47/316 Data mainly from organ transplant cohorts, including one cohort of $n = 221$ demonstrating both reduced gestation and birth weight	i) MMF remains contraindicated during pregnancy, and should be avoided in women planning pregnancy or switched to a pregnancy-compatible alternative at least 6 weeks before attempting to conceive (GRADE 1B, SOA 100%) ii) In cases of unintended conception, switch MMF to a pregnancy-compatible alternative and refer to local experts for further advice and risk assessment (GRADE 1B, SOA 100%) iii) MMF is not recommended while breastfeeding (GRADE 2C, SOA 99.7%)
IVIG	1 cc [248] 12 ct [48, 49, 74, 79, 127, 128, 133, 249–253] 1 Cochr [82] 1 cs [97] 3 cr [58, 110, 254]	403 (1st ≥13, 2nd/3rd ≥77)	10/178	No significant adverse effect noted	22/121 Overall, no increase in rate of major malformations attributable to drug, albeit limited data available	i) IVIG is compatible with pregnancy (GRADE 1B, SOA 99.5%) ii) IVIG is compatible with breastmilk exposure (GRADE 2C, SOA 100%)

All studies that provided quantitative and/or qualitative information on the safety of the relevant drug in pregnancy were included; however, numerical outcome data could only be collated from papers where the relevant outcome was clearly quantified. Details of how numerical data in this table were derived are shown in Supplementary Data S3, available at *Rheumatology* online.
cc: case control; Cochr: Cochrane review; cr: case report; cs: case series; CsA: ciclosporin; ct: cohort; MP: methylprednisolone; NR: not reported; nrt: non-randomized trial; Pred: prednisolone; rct: randomised controlled trial; SOA: strength of agreement; sr: systematic review; TAC: tacrolimus.

Table 3. Summary of maternal exposure to biological DMARDs and targeted synthetic DMARDs

Drug	Studies (type and number)	Pregnancy exposures (exposures per trimester)	Foetal losses/ total pregnancy outcomes	Pregnancy duration and birth weight	Malformations/total births	Recommendation (GRADE/Strength of agreement)
TNFi (combined data for all licenced drugs)	See individual drugs below, plus: 28 ct [277, 278, 295–298, 301–313, 315–323] 1 cs [279] 4 cc [172, 299, 300, 314]	7787 (1st ≥2929, 2nd/3rd ≥2150)	886/4192	No significant adverse effect noted overall	214/5157 Overall, no increase in rate of major malformations attributable to drug	i) Women with no/low disease activity established on a tumour necrosis factor inhibitor (TNFi) with known placental transfer (INF, ADA, GOL) do not need to be switched to an alternative TNFi with established minimal placental transfer (CZP) either before or during pregnancy (GRADE 1B, SOA 100%) ii) CZP is compatible with all three trimesters of pregnancy, has no to minimal placental transfer compared with other TNFi, and does not require any alteration to the infant vaccination schedule (GRADE 1B, SOA 100%) iii) Women considered to have low risk of disease flare on withdrawal of TNFi in pregnancy could stop INF at 20 weeks, ADA and GOL at 28 weeks, and ETA at 32 weeks so that a full-term infant can have a normal vaccination schedule, with rotavirus vaccination at 8 weeks as per the UK schedule (GRADE 1B, SOA 99.5%) iv) INF, ADA, ETA or GOL may be continued throughout pregnancy to maintain maternal disease control; in these circumstances, live vaccines should be avoided in infants until they are 6 months of age (GRADE 1B, SOA 100%) v) If a TNFi is stopped in pregnancy, it can be restarted as soon as practical post-partum in the absence of infections or surgical complications, regardless of breastfeeding status, to ensure control of maternal disease (GRADE 1C, SOA 100%) vi) TNFi are compatible with breastmilk exposure (GRADE 1C, SOA 100%)
CZP	2 ct [283, 284] 1 cs [285]	567 (1st ≥371, 2nd/3rd ≥335)	52/567	No significant adverse effect noted overall	9/488 Overall, no increase in rate of major malformations attributable to drug	See recommendations above
INF	9 ct [50, 260–263, 291–294] 8 cs [173, 264–270] 1 cr [271]	2645 (1st ≥1301, 2nd/3rd ≥92)	255/2484	No significant adverse effect noted overall	56/2090 Overall, no increase in rate of major malformations attributable to drug	See recommendations above
ETA	5 ct [50, 52, 260, 286, 287] 3 cs [100, 266, 272] 4 cr [108, 109, 273, 274] 1 rct [288]	821 (1st ≥475, 2nd/3rd ≥207)	73/383	No significant adverse effect noted overall	47/676 Overall, no increase in rate of major malformations attributable to drug	See recommendations above

Table 3. (continued)

Drug	Studies (type and number)	Pregnancy exposures (exposures per trimester)	Foetal losses/ total pregnancy outcomes	Pregnancy duration and birth weight	Malformations/total births	Recommendation (GRADE/Strength of agreement)
ADA	7 ct [50, 52, 252, 261, 280–282] 5 cs [99, 266, 268–270] 3 cr [271, 275, 276]	473 (1st ≥425, 2nd/3rd ≥298)	33/371	No significant adverse effect noted overall	30/397 Overall, no increase in rate of major malformations attributable to drug	See recommendations above
GOL	2 ct [289, 290]	166 (NR)	34/166	NR	3/115 Overall, no increase in rate of major malformations attributable to drug	See recommendations above
RTX	5 ct [50, 343, 344, 350, 354] 4 cs [345, 351–353] 4 cr [346–349]	316 (1st ≥13, 2nd/3rd ≥1)	68/293	No significant adverse effect noted	6/170 Overall, no increase in rate of major malformations attributable to drug	i) Limited evidence has not shown RTX to be teratogenic; however, there remains insufficient evidence to be confident that it is compatible with pregnancy. Consider stopping the drug at conception (GRADE 2C, SOA 99.3%) ii) RTX may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 99.7%) iii) If RTX is used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 98.7%) iv) Based on limited evidence, maternal treatment with RTX is compatible with breastmilk exposure (GRADE 2C, SOA 99.5%)
TOC	2 ct [358, 359] 2 cs [356, 357]	365 (1st ≥46, 2nd/3rd ≥2)	84/354	No significant adverse effect attributable to drug (data limited by confounding)	8/211 Overall, no increase in rate of major malformations attributable to drug	i) Limited evidence has not shown IL-6i to be teratogenic; however, there remains insufficient evidence to be confident that they are compatible with pregnancy. Consider stopping the drug at conception. Any exposure, however, during pregnancy is unlikely to be harmful (GRADE 2C, SOA 99.7%) ii) IL-6i may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 100%) iii) If IL-6i are used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 99.3%) iv) Based on limited evidence, maternal treatment with IL-6i is compatible with breastmilk exposure (GRADE 2C, SOA 100%)

Table 3. (continued)

Drug	Studies (type and number)	Pregnancy exposures (exposures per trimester)	Foetal losses/ total pregnancy outcomes	Pregnancy duration and birth weight	Malformations/total births	Recommendation (GRADE/Strength of agreement)
ANA	2 ct [50, 371] 4 cs [367, 369, 370, 372] 1 cr [368]	48 (1st ≥25, 2nd/3rd ≥40)	3/43	No significant adverse effect attributable to drug	2/41 (including one resulting in miscarriage at 30 weeks)	i) Limited evidence has not shown IL-1i to be teratogenic; however, there remains insufficient evidence to be confident that they are compatible with pregnancy. Consider stopping the drug at conception. Any exposure, however, during pregnancy is unlikely to be harmful (GRADE 2C, SOA 99.8%) ii) IL-1i may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 100%) iii) If IL-1i are used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 99.3%) iv) Based on limited evidence, maternal treatment with IL-1i is compatible with breastmilk exposure (GRADE 2C, SOA 100%)
CAN	1 cs [369]	8 (all 1st)	1/8	No significant adverse effect noted	0/7	See recommendations above
ABA	1 cs [175] 1 cr [349] 2 ct [375, 376]	99 (1st ≥145, 2nd/3rd ≥10)	49/187	No significant adverse effect attributable to drug (data limited by confounding)	10/104 Overall, no pattern of malformations attributable to drug	i) Limited evidence has not shown ABA to be teratogenic; however, there remains insufficient evidence to be confident that it is compatible with pregnancy. Consider stopping the drug at conception. Any exposure, however, during pregnancy is unlikely to be harmful (GRADE 2C, SOA 99.3%) ii) ABA may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 99.3%) iii) If ABA is used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 99.3%) iv) Based on limited evidence, maternal treatment with ABA is compatible with breastmilk exposure (GRADE 2C, SOA 99.5%)

Table 3. (continued)

Drug	Studies (type and number)	Pregnancy exposures (exposures per trimester)	Foetal losses/ total pregnancy outcomes	Pregnancy duration and birth weight	Malformations/total births	Recommendation (GRADE/Strength of agreement)
BEL	1 ct [380]	66 (NR)	18/66	No significant adverse effect attributable to drug (data limited by confounding)	3/33 Overall, no pattern of malformations attributable to drug	i) Limited evidence has not shown BEL to be teratogenic; however, there remains insufficient evidence to be confident that it is compatible with pregnancy. Consider stopping the drug at conception. Any exposure, however, during pregnancy is unlikely to be harmful (GRADE 2C, SOA 99.3%) ii) BEL may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 99.5%) iii) If BEL is used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 98.8%) iv) Based on limited evidence, maternal treatment with BEL is compatible with breastmilk exposure (GRADE 2C, SOA 99.5%)
SEC	2 ct [387, 388]	244 (1st ≥161, 2nd/3rd NR)	26/125	No significant adverse effect noted	2/54 Overall, no pattern of malformations attributable to drug	i) Limited evidence has not shown IL-17i to be teratogenic; however, there remains insufficient evidence to be confident that they are compatible with pregnancy. Consider stopping the drug at conception. Any exposure, however, during pregnancy is unlikely to be harmful (GRADE 2C, SOA 99.3%) ii) IL-17i may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 99%) iii) If IL-17i are used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 99.3%) iv) Based on limited evidence, maternal treatment with IL-17i is compatible with breastmilk exposure (GRADE 2C, SOA 99.5%)
IXE	1 ct [389]	18 (NR)	5/18 (spontaneous and induced)	No significant adverse effect noted	0/8 Overall, no pattern of malformations attributable to drug	See recommendations above

(continued)

Table 3. (continued)

Drug	Studies (type and number)	Pregnancy exposures (exposures per trimester)	Foetal losses/ total pregnancy outcomes	Pregnancy duration and birth weight	Malformations/total births	Recommendation (GRADE/Strength of agreement)
UST	2 ct [391, 392] 1 cs [393]	517 (1st ≥31, 2nd/3rd ≥10)	92/517	No significant adverse effect noted	17/375 Overall, no pattern of malformations attributable to drug	i) Limited evidence has not shown UST to be teratogenic; however, there remains insufficient evidence to be confident that it is compatible with pregnancy. Consider stopping the drug at conception. Any exposure, however, during pregnancy is unlikely to be harmful (GRADE 2C, SOA 99.3%) ii) UST may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 98.8%) iii) If UST is used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 99.3%) iv) Based on limited evidence, maternal treatment with UST is compatible with breastmilk exposure (GRADE 2C, SOA 99.5%)
TOF	1 ct [397]	116 (all 1st, 2nd/3rd NR)	15/72	No significant adverse effect noted	2/44 Overall, no pattern of malformations attributable to drug	i) There are insufficient data to make a recommendation on JAKi use during pregnancy and they should be stopped at least two weeks before planned conception (GRADE 2C, SOA 99.5%) ii) There are insufficient data to recommend JAKi in breastfeeding and, given they are likely to transfer into breastmilk, they should be avoided (GRADE 2C, SOA 99.5%)

All studies that provided quantitative and/or qualitative information on the safety of the relevant drug in pregnancy were included; however, numerical outcome data could only be collated from papers where the relevant outcome was clearly quantified. Details of how numerical data in this table were derived are shown in Supplementary Data S3, available at *Rheumatology* online.

Table 4. Summary of pregnancy outcomes after paternal exposure

Drug	Studies included (type and number)	Pregnancy exposures	Adverse pregnancy outcomes (foetal losses or malformations)	Recommendation (GRADE/Strength of agreement)
HCQ	1 ct [52] 1 cs [404]	13	No increase	Paternal exposure to HCQ is compatible with pregnancy (GRADE 2C, SOA 99.3%)
CS	5 ct [52, 405–407, 411] 2 cs [404, 408]	4507	No increase	Paternal exposure to prednisolone is compatible with pregnancy (GRADE 1B, SOA 99.3%)
SSZ	3 ct [52, 407, 412] 1 cc [409]	237	No increase	Men who take SSZ may have reduced fertility. There is little evidence to suggest that SSZ should be stopped pre-conception, unless conception is delayed by >12 months when stopping SSZ should be considered along with other causes of infertility (GRADE 1C, SOA 99.0%)
LEF	1 ct [52] 1 cr [413]	2	No increase	Paternal exposure to LEF is compatible with pregnancy (GRADE 2C, SOA 99.3%)
AZA	9 ct [52, 185, 187, 216, 405–407, 414, 415] 1 cc [409] 2 cs [404, 408]	3282[a]	No increase	Paternal exposure to AZA is compatible with pregnancy (GRADE 1B, SOA 99.3%)
MTX	10 ct [52, 184–189, 405, 407] 3 cs [404, 410], 1 cr [428]	2289	No increase	Paternal exposure to low-dose (≤25 mg/week) MTX is compatible with pregnancy (GRADE 1B, SOA 99.3%)
CsA	3 ct [185, 406, 416] 2 cs [408, 410]	501[a]	No increase	Paternal exposure to CsA is compatible with pregnancy (GRADE 1C, SOA 99.3%)
TAC	3 ct [406, 416, 417]	41[a]	No increase	Paternal exposure to TAC is compatible with pregnancy (GRADE 2C, SOA 99.3%)
CYC	No data meeting inclusion criteria		Known to affect male fertility; evidence of an adverse impact on germ cell development and male-mediated teratogenicity from animal studies	Due to the adverse effect of CYC on male fertility, semen cryopreservation is recommended for men prior to paternal exposure (GRADE 1C, SOA 99.5%)
MMF	3 ct [185, 246, 247] 3 cs [406, 416, 426]	292	No increase	Paternal exposure to MMF is compatible with pregnancy (GRADE 2C, SOA 99.3%)
TNFi	13 ct [52, 263, 293, 298, 306, 405, 412, 427, 430–434] 2 cs [404, 410] 2 cr [428, 429] 1 cc [409]	751	No increase	Paternal exposure to TNFi is compatible with pregnancy (GRADE 1C, SOA 99.3%)
RTX	1 ct [343]	11	No increase	Paternal exposure to RTX is compatible with pregnancy (GRADE 2C, SOA 99.3%)
IL-6i	1 ct [359]	15 (TOC)	No increase	Paternal exposure to IL-6i is compatible with pregnancy (GRADE 2C, SOA 99.3%)
IL-1i	1 ct [369]	5 (ANA) 6 (CAN)	No increase	Paternal exposure to IL-1i is compatible with pregnancy (GRADE 2C, SOA 99.3%)
ABA	1 ct [375]	10	No increase	Paternal exposure to ABA is compatible with pregnancy (GRADE 2C, SOA 99.3%)
IL-17i	2 ct [387, 389]	54 (SEC) 34 (IXE)	No increase	Paternal exposure to IL-17i is compatible with pregnancy (GRADE 2C, SOA 99.3%)
JAKi	1 ct [398]	87 (TOF)	No increase	Paternal exposure to JAKi is compatible with pregnancy (GRADE 2C, SOA 99.3%)

All studies that provided quantitative and/or qualitative information on the safety of the relevant drug following paternal exposure were included. Details of how numerical data in this table were derived are shown in Supplementary Data S3, available at *Rheumatology* online.

[a] Minimum number of pregnancy exposures to drug; additional exposures were described in some studies but could not be separated from grouped study data.

ABA: abatacept; ANA: anakinra; BEL: belimumab; CAN: canakinumab; cc: case control; cr: case report; cs: case series; CS: corticosteroids; CsA: ciclosporin; ct: cohort; IL-1i: IL-1 inhibitors; IL-6i: IL-6 inhibitors; IL-17i: IL-17 inhibitors; IXE: ixekizumab; JAKi: Janus kinase inhibitors; NR: not reported; RTX: rituximab; SEC: secukinumab; SOA: strength of agreement; TAC: tacrolimus; TNFi: TNF-alpha inhibitor; TOC: tocilizumab; TOF: tofacitinib; UST: ustekinumab.

autoimmune rheumatic disorders, the benefits of treatment during pregnancy will likely outweigh this risk.

Importantly, a more recent study (published after our search date) of pregnant women prospectively enrolled into MotherToBaby/Organisation of Teratology Information Specialists (OTIS) pregnancy studies, compared outcomes for HCQ-exposed pregnancies ($n = 279$) with disease-matched ($n = 279$) and healthy comparator ($n = 279$) HCQ-unexposed groups [65]. Reassuringly, this study found no evidence of an increased risk for structural defects or other adverse outcomes with HCQ at any dose (average 325 mg/day; range 100–800 mg/day), except for an isolated finding of reduced head circumference at birth with HCQ exposure, which was not thought to be of any clinical significance.

Therefore, advice on HCQ dosage in pregnancy relates to general guidance for reducing ophthalmic risk outside of pregnancy to a maximum of 400 mg/day, as pharmacokinetic changes in pregnancy reduce the reliability of weight-based dosing [66]. Ultimately, it is important to maintain HCQ during pregnancy, as discontinuation of this drug in pregnancy may increase risk of disease flares and foetal loss [67]. Disease flares would increase the need for alternative medications with more potential risks for mother or baby in pregnancy.

Previous studies of breastmilk exposure to HCQ were mostly limited to case reports, showing that <1% of the maternal dose of HCQ was found in breastmilk [68]. Three more recent studies of HCQ use ($n = 195$) confirmed very low concentrations of HCQ in breastmilk and no adverse effects on breastfed infants [36, 69, 70]. There remain limited studies of long-term outcomes in children, but no adverse immunological or clinical findings have been reported [36, 43].

Recommendations for hydroxychloroquine in pregnancy and breastmilk exposure

i) HCQ remains the antimalarial of choice in women planning a pregnancy with rheumatic disease in need of treatment, and should be continued during pregnancy at a dose of ≤400 mg/day (GRADE 1B, SOA 100%).
ii) HCQ is compatible with breastmilk exposure (GRADE 1B, SOA 99.5%).

Corticosteroids

Corticosteroids used to treat rheumatic disease (prednisolone, prednisone and methylprednisolone) are metabolized in the placenta, and so 10% or less of the active drug reaches the foetus. Previously, we identified 47 studies on prednisolone and found it to be compatible with pregnancy and breastmilk exposure [1]. Studies of corticosteroid use in pregnancy were confounded by multiple concomitant medications and use in high-risk pregnancies; particularly the fluorinated steroids, which are used to prevent or treat preterm labour and complications such as foetal lung immaturity. Therefore, we searched for further evidence on corticosteroids used to treat rheumatic disease and identified additional studies: 11 on prednisolone with ($n = 1218$) pregnancies [31, 71–80] and one on methylprednisolone with ($n = 12$) pregnancies [81]. This evidence was combined with the previous studies: 47 on prednisolone ($n = 1503$) [43, 46, 48, 51–53, 55, 57, 59–61, 82–117]; 31 on dexamethasone ($n = 11\,214$) [48, 54, 88, 97, 118–144]; 27 on betamethasone ($n = 27\,746$) [118–120, 125, 126, 128, 130, 131, 140, 143, 145–162]; and 10 on general corticosteroid use ($n = 785$) [42, 49, 50, 54, 163–168].

Studies on the use of methylprednisolone in pregnancy were not specifically sought in the previous guideline because it is generally used as rescue therapy for severe disease. Compared with prednisolone, parenteral administration of methylprednisolone has a prolonged duration of action with similar rates of placental transfer to prednisolone [169].

Previously, we found that following prednisolone (or unspecified corticosteroid) exposure, average pregnancy duration in the majority of randomized controlled trial (RCT), case-control, cohort and case-series studies (where reported) was usually term, at ≥37 weeks [43, 51, 84, 85, 88, 92, 94, 96, 101, 102, 104, 105]. Other studies reporting ≤37-week delivery were confounded by factors such as maternal disease and concomitant medications [46, 57, 59, 60, 86, 87, 99, 106, 113, 117, 163, 165]. Birth weights followed a similar pattern and were affected by preterm deliveries and confounding factors, as described above. For instance, prednisolone exposure in those RCTs, cohorts, case-control studies and case series which reported average gestations of ≥37 weeks, average birth weights ranged from 2.6–3.4 kg [43, 46, 51, 85, 88, 92, 94, 96, 101, 104, 105]. Overall, prednisolone itself was not felt to have contributed to low birth weight (LBW) in any study [1].

High rates of maternal complications compatible with underlying disease were previously reported for prednisolone and dexamethasone, but none were specifically attributed to these medications [1]. The major congenital malformations observed with prednisolone were frequently confounded by concomitant teratogenic drug exposure, such as MMF [116], and the overall incidence was not significantly higher than in drug-free controls. Studies reporting major malformations with fluorinated steroid exposure [e.g. patent ductus arteriosus (PDA), blindness and deafness [126, 145]] did not attribute them to steroid therapy. Furthermore, in the majority of cases, the steroids were used for treatment of underlying conditions such as preterm delivery [126], where steroids were found to be beneficial in improving outcomes, or treatment of maternal autoantibody-mediated cardiomyopathy [133]. A large study analysing 832 636 live births did not show an increased risk of orofacial cleft palate with the use of corticosteroids in pregnancy [164]. foetal loss in studies of prednisolone and fluorinated steroids was attributed to underlying disease rather than steroid therapy, such as in APS [105] and complete atrio-ventricular block [170].

Most (8/11) of the additional studies on maternal prednisolone exposure that we found in our updated search did not identify any adverse effects of prednisolone use on pregnancy outcomes [31, 72–74, 76–79]. In contrast, a population-based study from Norway exploring the associations between disease activity and medications with offspring birth weight, pre-eclampsia and preterm birth in SLE found prednisolone use to be significantly associated with lower birth weight, increased risk of pre-eclampsia, and a 3-fold increase in preterm birth [71]. A conference abstract reported that continuation of high-dose glucocorticoids during 164 pregnancies increased the risks of preterm birth, low birth weight and preterm premature rupture of membranes (PPROM) at prednisolone cut-off doses of 7.5 mg, 6.7 mg, 5.0 mg per day, respectively [75]. In contrast, another conference abstract of 143 SLE pregnancies found that foetal complications were associated with prednisone >25 mg, and that low (10 mg/day) to moderate (10–24 mg/day) doses of prednisone during pregnancy were not associated with adverse foetal outcomes [77]. Similarly, the largest prospective study of SLE pregnancy outcomes did

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

not identify prednisolone ≤20 mg/day as a risk factor for adverse pregnancy outcomes [31].

UKTIS notes that many of the studies reporting pregnancy outcomes following gestational exposure to systemic corticosteroids are limited by a lack of stratification to account for differing doses, treatment duration and steroid potencies, as well as confounding by maternal disease [171]. It concludes that preterm delivery may be associated with gestational exposure to systemic corticosteroids, and further well-controlled studies are required to address this question. Therefore, an increased risk of adverse foetal effects following use of high-dose/potency corticosteroids, or use for extended periods, cannot be ruled out.

Based on limited evidence, prednisone, prednisolone and methylprednisolone are considered compatible with breastmilk exposure [1]. There remain few breastmilk exposure studies. One study, comprising 19 pregnancy and breastmilk exposures, found that prednisone and prednisolone exhibit dose- and concentration-dependent pharmacokinetics during pregnancy, and infant exposure to these agents via breastmilk is minimal [76]. Another study of 12 patients with multiple sclerosis found the transfer of methylprednisolone into breastmilk to be low even when maternal serum concentration levels were highest at the end of an infusion, and although these levels were not considered to pose a threat to the infant, they state that mothers may choose to wait two to four h to further limit an infant's exposure [81].

Previously, long-term follow-up studies had not reported any adverse events after prednisolone exposure in pregnancy [1]. Two additional studies did not report any adverse events from 9–12 months of post-partum follow-up of 227 non-rheumatic disease pregnancies exposed to prednisolone [78, 79].

Recommendations for corticosteroids in pregnancy and breastmilk exposure

i) Prednisolone is compatible with pregnancy and is the preferred corticosteroid in the treatment of maternal rheumatological disease in pregnancy and requires shared care with obstetric teams to monitor maternal blood pressure and blood glucose (GRADE 1B, SOA 100%).
ii) Where possible, the dose of prednisolone should be <20 mg/day and tapered to the minimum effective dose to control maternal disease, in conjunction with steroid-sparing drugs compatible with pregnancy (GRADE 1C, SOA 99.5%).
iii) Prednisolone is compatible with breastmilk exposure (GRADE 1B, SOA 100%).
iv) Methylprednisolone has similar rates of placental transfer to prednisolone and would therefore be expected to be compatible with pregnancy and breastmilk exposure (GRADE 2C, SOA 99%).

Conventional synthetic DMARDs and immunosuppressive therapies

Methotrexate

MTX is contraindicated in pregnancy and was previously recommended to be stopped at least three months in advance of conception [68]. UKTIS considers MTX risk in pregnancy to be dependent on its use at high (>25 mg per week) or low (≤25 mg per week) dosages [171]. Rheumatology usage of MTX to treat inflammatory arthritis falls into the low-dose category and is far removed from the high doses used as a chemotherapeutic agent in the treatment of various cancers (e.g. >500 mg/m^2) or as an abortifacient at 50 mg/m^2. UKTIS concludes that exposure to high-dose MTX in early pregnancy confers a risk of severe embryopathy (including craniofacial defects, malformations of the digits and defects of the spine and ribs) in the foetus, and the option of termination of pregnancy should be discussed with the patient. In contrast, for exposure to lower doses of MTX prior to conception, additional foetal monitoring is advised, as well as counselling of women and their partners about the lack of available data to facilitate quantification of risk of adverse pregnancy outcomes.

Previously, we identified a high proportion of major anomalies following MTX (and other DMARD) exposure, predominantly during the first trimester of pregnancy, in 27 pregnancies from 10 studies [50, 52, 91, 172–178]. An additional 12 studies of MTX exposure in 2765 pregnancies were identified: six maternal studies [37, 179–183] and six paternal studies [184–189].

Several studies reported on the risks of pre-conceptual and pregnancy exposure to MTX. Data from the National Birth Defects Prevention Study, a US case-control study of major birth defects, reported that 4/10 113 (0.04%) mothers of foetus/infants without major birth defects (controls) had been exposed to MTX, compared with 16/27 623 (0.06%) mothers of live-born infants with a major birth defect (cases) who had been exposed to MTX [181]. The dose of MTX was not reported, but indications included a neoplasm of endocrine glands and so was presumably of high dose in at least one case. Of the 16 cases with major birth defects, 15 were exposed from three months pre-conception to the end of the first trimester.

A cohort study of 240 SLE pregnancies in whom 36.8% were exposed to MTX before and during the first trimester reported an increased risk of foetal complications [182]. A large prospective observational multicentre cohort study of 324 pregnancies exposed to MTX found an increase in the cumulative incidence of spontaneous miscarriage (42.5%) and major congenital anomalies (6.6%) among pregnancies ($n = 188$) exposed to a median dose of 10 mg/week of MTX after a median of 4.3 weeks post-conception [179]. This difference reached statistical significance when compared with a cohort of women without autoimmune diseases, but not when compared with a disease-matched cohort. No increased risk of miscarriage or major congenital anomaly was found in pregnancies ($n = 136$) exposed to a median dose of 15 mg/week of MTX that was stopped three months pre-conception.

Not all studies reported increased risks with MTX exposure. A study of pre-conception use of MTX on miscarriage rates in 114 RA pregnancies, compared with 48 MTX-unexposed RA pregnancies, did not find a statistically significant association between miscarriage and MTX use [180]. An analysis of 18 pregnancies exposed to MTX (≤20 mg/week) from up to one year pre-conception and in the first trimester found a high percentage of live-born children with no malformations [183]. Analysis of 23 first trimester exposures to low-dose MTX, identified from three United States health plan databases, did not reveal a significant increase in the risk of congenital malformations, foetal death or neonatal complications in women with chronic autoimmune disease, compared with those who received MTX before, but not during, pregnancy [37].

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

These studies provide some evidence that a 3-month MTX-free interval prior to conception might not be required. Therefore, unintentional exposure to low-dose MTX during the peri-conceptional period confers minimal risk in unintended pregnancy exposures, and so termination of pregnancy is not routinely recommended for MTX exposure unless it is maternally requested due to unplanned pregnancy [37, 180, 183].

Studies of MTX in breastfeeding remain very limited. Although they did not meet our inclusion criteria, we identified two case reports that found low levels of MTX in breastmilk and no adverse effects on the breastfed infants [190, 191]. LactMed describes low levels of MTX in breastmilk and conflicting expert opinion on whether it can safely be used during breastfeeding [192]. It states that withholding breastfeeding for 24 h after a weekly low-dose of MTX may decrease the infant's dose by 40%, and that if breastfeeding is undertaken during long-term, low-dose MTX use, monitoring of the infant's complete blood count and differential could be considered.

Post-partum follow-up of up to 14 months after first trimester MTX exposure was reported in three infants with long-term complications of foetal MTX syndrome, including semi lobar holoprosencephaly, cardiac abnormalities, tracheostomy and requirement for antiepileptic therapy [176, 177].

Recommendations for methotrexate in pregnancy and breastmilk exposure

i) MTX at any dose should be avoided in pregnancy and stopped at least one month in advance of planned conception, when it should be switched to another pregnancy-compatible drug to ensure maintenance of maternal disease suppression (GRADE 1A, SOA 98%).
ii) In women treated with low-dose (≤25 mg/week) MTX within one month prior to conception, folic acid supplementation (5 mg/day) should be continued up to 12 weeks of pregnancy (GRADE 1B, SOA 99.5%).
iii) In unintended pregnancy on low-dose (≤25 mg/week) MTX, there is minimal risk to the foetus; the drug should be stopped immediately, folic acid supplementation (5 mg/day) continued, and a careful evaluation of foetal risk with early referral to a foetal medicine department considered (GRADE 1C, SOA 100%).
iv) Although only minute amounts of MTX are excreted into breastmilk, MTX cannot be recommended in breastfeeding because of theoretical risks and insufficient data on outcomes (GRADE 2C, SOA 99%).

Sulfasalazine

Previously, we recommended that SSZ is compatible with pregnancy and breastmilk exposure and can be continued with adequate folic acid supplementation (5 mg/day) [1]. This recommendation was based on six publications reporting SSZ exposure in 178 pregnancies in patients with RA, osteoporosis and ankylosing spondylitis (AS) [46, 50, 52, 55, 62, 193]. These studies contained limited information relating to miscarriage rate, pregnancy duration, birth weight or malformation rate; overall, however, there were no significant adverse effects highlighted that were considered to be directly attributable to SSZ. We did not identify any additional studies on the use of SSZ in pregnancy, breastmilk exposure or paternal exposure.

UKTIS does not identify any specific risks with SSZ exposure. It comments that although high-dose folic acid (5 mg/day) is generally recommended, no studies have investigated whether there is increased benefit of this higher dose of folic acid compared with a standard dose of 400 micrograms/day.

Minimal amounts of SSZ are expressed in breastmilk, and it can be used during breastfeeding if the infant is full term and healthy, although it should be avoided in ill, stressed or premature infants, and in infants with hyperbilirubinaemia or glucose-6-phosphate dehydrogenase deficiency [68].

Recommendations for sulfasalazine in pregnancy and breastmilk exposure

i) SSZ is compatible throughout pregnancy, with folic acid 5 mg/day recommended in the periconception period and during the first trimester (GRADE 1B, SOA 100%).
ii) SSZ is compatible with breastmilk exposure in healthy, full-term infants (GRADE 1C, SOA 99.5%).

Leflunomide

Based upon limited evidence, we previously found that LEF may not be a human teratogen, but there was insufficient evidence to support its compatibility in human pregnancy, so our recommendation was that LEF is not the DMARD of choice in women planning pregnancy [1]. This recommendation was based on data from seven studies [50, 91, 194–198] reporting on 111 pregnancies exposed to LEF (discontinued in almost all cases in the first trimester, and frequently followed by a cholestyramine washout). Overall, the findings were largely reassuring, with no direct evidence of human teratogenicity.

We identified three additional studies of 703 pregnancies exposed to LEF at various stages of pregnancy, with varying exposure to washout and/or plasma testing of LEF metabolites, which did not find an increased risk of adverse pregnancy outcomes compared with the general population [199–201]. Although it was not included within our systematic review, pregnancy outcomes have been reported for teriflunomide—the principal active metabolite responsible for leflunomide's activity *in vivo*—which, at recommended doses, results in a similar range of plasma concentrations to leflunomide [202]. The known outcomes from 222 pregnancy exposures to teriflunomide for relapsing forms of multiple sclerosis also found outcomes consistent with the general population [202]. Overall, these findings do not indicate a teratogenic risk of LEF in human pregnancies. The practicality of previous recommendations regarding the testing of plasma levels of teriflunomide has been questioned [199], and testing is not currently routinely available in the UK.

We did not identify any data on breastmilk exposure to LEF, and no information is available in LactMed [192].

Recommendations for leflunomide in pregnancy and breastmilk exposure

i) LEF may not be a human teratogen but there remains insufficient evidence to support use at the time of conception or during pregnancy (GRADE 1B, SOA 98%).
ii) Women on LEF considering pregnancy should stop and undergo a standard cholestyramine washout procedure, and switch to alternative medication compatible with pregnancy (GRADE 1B, SOA 98.8%).
iii) If unintended conception occurs on LEF, the drug should be stopped immediately and a standard cholestyramine washout procedure given, with early referral

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

to a foetal medicine department considered (GRADE 1B, SOA 99%).
iv) LEF is not recommended while breastfeeding (GRADE 1C, SOA 99.5%).

Azathioprine

Previously, we recommended that AZA is compatible with pregnancy at doses ≤2 mg/kg, with breastmilk exposure and with paternal exposure [1]. These recommendations were based on 28 studies [45, 50–52, 55, 61, 83, 88, 90, 92, 93, 95, 99, 101, 102, 107, 135, 172, 173, 203–211] in 738 AZA-exposed pregnancies, which included a wide range of diagnoses and concomitant medications, compared with 1121 disease-matched and 667 healthy controls. These data did not demonstrate an increased risk of miscarriage, preterm birth, low birth weight or congenital malformation due to AZA exposure in pregnancy.

We identified an additional nine studies of 3699 pregnancy exposures to AZA: six maternal studies [31, 78, 212–215] and three paternal studies [185, 187, 216]. Overall, the findings from maternal exposures ($n = 1019$) to AZA did not identify any adverse pregnancy outcomes. One study, reporting on AZA metabolism in 30 IBD pregnancies, measured active metabolites and found only 6-thioguanine nucleotide (6-TGN) but not 6-mercaptopurine (6-MP) in umbilical cord blood at delivery; no major teratogenicity was observed, although 60% of the infants had anaemia, which was suspected to be due to maternal thiopurine use [214]. Two of these studies extended follow-up to 3 months and nearly 10 years, without any adverse effects being reported. The majority of studies did not specify the mean/median dose of AZA utilized in the study populations, and there is no clear evidence regarding a dose limit. Use of AZA at an effective dose should be supported by monitoring of blood tests, following local guidelines.

Based on our previous evidence from 26 infants breastfed by mothers on AZA or 6-MP, minimal amounts of AZA were detected in breastmilk, and no adverse effects were identified [101, 209–211]. We did not identify any new studies of breastmilk exposure to AZA. LactMed states that avoiding breastfeeding for 4 h after maternal ingestion of AZA should markedly reduce the dose received by the infant in breastmilk [192]. In routine clinical practice, there is no concern in the management of solid organ transplant patients who breastfeed on this drug [217].

Recommendations for azathioprine in pregnancy and breastmilk exposure

i) AZA is compatible throughout pregnancy (GRADE 1B, SOA 100%).
ii) AZA is compatible with breastmilk exposure (GRADE 2C, SOA 99.5%).

Ciclosporin

An earlier consensus document reviewed evidence from >800 human pregnancies exposed to ciclosporin (CsA) [68]. Our previous search from 2005 onwards identified a further 13 studies/reports [43, 50, 51, 54, 88, 92, 93, 95, 101, 135, 136, 165, 218] of 98 pregnancies in patients with a variety of diseases and multiple concomitant medications who had been exposed to CsA at 2–6 mg/kg during pregnancy. Reports of increased rates of preterm delivery and low birth weight were confounded by maternal disease and concomitant medications, and there was no evidence of an increased malformation risk [1]. Comorbidities, such as hypertension, pre-eclampsia and gestational diabetes mellitus, were reported at higher incidences than the general population. Based upon this evidence, CsA was considered compatible with pregnancy at the lowest effective dose, with monitoring of blood pressure, blood glucose and renal function [68]. UKTIS draws a similar conclusion [171].

We identified an additional five studies of 550 pregnancy exposures [182, 185, 219–221]. Three studies reported on maternal exposure [182, 219, 220]. A cohort study of 240 SLE pregnancies, in whom 50% were exposed to CsA before and during the first trimester, increased the risk of pancytopenia and/or pre-eclampsia in maternal outcomes [182]. A single-centre experience of outcomes of pregnancy ($n = 117$) following liver transplantation did not find any difference between those on CsA ($n = 34$) compared with tacrolimus ($n = 81$), and so did not attribute these outcomes to medication [219]. A study of the efficacy and safety of CsA in 29 pregnancies of patients with systemic autoimmune diseases did not find an increased risk of maternal–foetal complications, and stated that it should be continued in patients who benefit from therapy [220].

Previously identified studies described small amounts of CsA in breastmilk and almost universally undetectable blood levels in infants [68, 218], without any adverse effects reported during breastmilk exposure. We found a further study that reported low transfer of CsA and its metabolites into the breastmilk of seven post-transplant mothers in the first two days post-partum, although this study was not designed to make a corresponding assessment of drug safety [221]. LactMed recommends that breastfed infants should be monitored if CsA is used during lactation, possibly with measurement of serum levels if there is a concern for toxicity [192]. In routine clinical practice, there is no concern in the management of solid organ transplant patients who breastfeed on this drug [217].

No additional studies of long-term follow-up were identified to those found previously on 10 infants exposed to CsA *in utero*, which reported no complications at 11–14 months [43, 54, 135].

Recommendations for ciclosporin in pregnancy and breastmilk exposure

i) CsA is compatible throughout pregnancy with monitoring of maternal blood pressure, renal function, blood glucose and drug levels (GRADE 1B, SOA 100%).
ii) CsA is compatible with breastmilk exposure (GRADE 2C, SOA 99.7%).

Tacrolimus

Based upon previous consensus [68, 222] and our previous review of six studies [92, 93, 99, 107, 116, 223] of 26 pregnancies exposed to tacrolimus and two breastmilk exposure studies [223, 224], tacrolimus was considered compatible with pregnancy and breastmilk exposure. There were complex confounding issues in many of these studies and, overall, no adverse outcomes were considered to be directly attributable to tacrolimus [1].

We found additional evidence from eight studies of 489 pregnancy exposures to tacrolimus [219, 225–231]. Studies

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

of maternal outcomes, mostly from solid organ transplant recipients, reported varying incidences of adverse maternal-foetal outcomes, but these outcomes were confounded by transplant-associated comorbidities and concomitant immunosuppression, particularly MMF [219, 225, 227–231].

UKTIS concludes that the available data do not suggest an association between spontaneous miscarriage, congenital malformation or intrauterine death and exposure to tacrolimus during pregnancy, but data are limited and potentially confounded; therefore, an increased risk of these outcomes cannot be excluded [171].

Previously, we found studies reporting low levels of tacrolimus in umbilical cord blood and breastmilk in small numbers of breastfed infants without any adverse effects [223, 224]. These findings were confirmed in an additional study of 13 breastfed infants of mothers with SLE [225]. This study found concentrations of tacrolimus in the umbilical cord blood were lower than those in the maternal blood; the relative infant dose in breastfed infants of tacrolimus was <1%, and the level of tacrolimus in infant blood was below detectable limits. LactMed suggests that exclusively breastfed infants should be monitored [192]. In routine clinical practice, there is no concern in the management of solid organ transplant patients who breastfeed on this drug [217].

Recommendations for tacrolimus in pregnancy and breastmilk exposure

i) Tacrolimus is compatible throughout pregnancy with monitoring of maternal blood pressure, renal function, blood glucose and drug levels (GRADE 2B, SOA 100%).
ii) Tacrolimus is compatible with breastmilk exposure (GRADE 2C, SOA 99.8%).

Cyclophosphamide

CYC is a known human teratogen and is gonadotoxic in men and women [68]. Our previous findings from reports of predominantly first trimester use of CYC in nine pregnancies, revealed multiple adverse outcomes in mothers with severe maternal disease and multiple concomitant medications [102, 106, 111, 167, 168]. No maternal complications of CYC were reported. The nine pregnancies ended in two first trimester miscarriages, six healthy infants and one major congenital anomaly (Klippel–Feil syndrome). Follow-up to 87–90 months in four live births reported normal development in three children [102] and the single case of Klippel–Feil syndrome [111].

We found an additional study of pregnancies ($n = 11$) in women with multiple sclerosis who had been exposed to CYC prior to conception [232]; 10 women had a successful delivery [five preterm delivery and one small for gestational age (SGA)], while one underwent elective termination. It should be noted, however, that the time between the last dose of CYC and conception in this study was an average of 3.7 ± 1.5 years (range 0.33–5.9 years).

Although it did not meet our inclusion criteria, one case report analysed breastmilk levels of CYC in a women with multiple sclerosis [233]. CYC levels in breastmilk samples were measured after IV CYC at a dose of 2.8 g, with relatively low levels identified in the milk. The authors reported an average relative infant dose for a period of four days that varied from 4.7% at day 1 to 0.9% at day 4.

Recommendations for cyclophosphamide in pregnancy and breastmilk exposure

i) CYC is a known teratogen and gonadotoxic, and therefore should only be considered in pregnancy in cases of severe life/organ-threatening maternal disease when there is appreciable risk of maternal and foetal morbidity and mortality without this therapy (GRADE 1B, SOA 99.5%).
ii) CYC is not recommended while breastfeeding (GRADE 2C, SOA 100%).

Mycophenolate mofetil

MMF is a known teratogen and is recommended to be stopped at least 6 weeks before a planned pregnancy [68, 222]. It is rapidly absorbed following oral administration and hydrolysed to form the active ingredient, mycophenolic acid (MPA). This active metabolite has a mean apparent half-life of 17 h after a 1 g oral dose of MMF, and undergoes enterohepatic circulation, with a secondary plasma peak at 6–12 h after an oral or intravenous dose [234].

We previously reviewed data from 16 studies/reports [57, 60, 92, 95, 99, 113, 114, 116, 208, 235–241] of 90 pregnancies exposed to MMF, mostly from renal transplant patients in whom there was concomitant exposure to prednisolone and tacrolimus. Increased rates of premature delivery, low birth weight and major congenital malformations were reported, including malformations typical for the previously described MMF embryopathy (including cleft lip and/or palate, microtia with aural atresia, micrognathia and ocular anomalies) [1].

Our updated search found eight further studies of 934 pregnancy exposures to MMF: five maternal exposure studies [215, 242–245] and three paternal exposure studies [185, 246, 247]. The five studies of maternal exposure in pregnancies ($n = 714$) all reported increased risks of miscarriage and birth defects, with 351 foetal losses, eight stillbirths and 38 cases of congenital malformation [215, 242–245]. These studies were mostly of first trimester exposure, with three including second and third trimester exposures. One study, however, found that following discontinuation of MMF within 6 weeks of conception, outcomes including the rates of birth defects and miscarriages were similar to pregnancies not exposed to MMF [245].

UKTIS describes the increased risks of first trimester pregnancy loss, as well as major congenital anomalies, and states that women of childbearing potential who are prescribed MMF or MPA should be informed of the associated risks to the foetus and, therefore, the importance of adequate contraception. It notes that European Medicines Agency guidelines for male and female patients, published in October 2015 following a periodic safety update review, recommend additional measures to prevent foetal exposure to MMF and should be read prior to prescribing MMF [171].

As in our previous search, we did not identify any data on breastmilk exposure. Similarly, LactMed reports that no information is available on the excretion of MMF into breastmilk, and that a few infants have reportedly been breastfed during MMF therapy with no adverse effects reported [192].

We did not identify any additional long-term follow-up data to that previously found of one case of ‘small for age’ with otherwise normal development [57], and another study

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

reporting on 3/6 exposed children (one with normal development, one who required hearing aids, and one who had motor and speech delay) [99].

Recommendations for mycophenolate mofetil in pregnancy and breastmilk exposure

i) MMF remains contraindicated during pregnancy, and should be avoided in women planning pregnancy or switched to a pregnancy-compatible alternative at least 6 weeks before attempting to conceive (GRADE 1B, SOA 100%).
ii) In cases of unintended conception, switch MMF to a pregnancy-compatible alternative and refer to local experts for further advice and risk assessment (GRADE 1B, SOA 100%).
iii) MMF is not recommended while breastfeeding (GRADE 2C, SOA 99.7%).

Intravenous immunoglobulin

IVIG is considered to be compatible with pregnancy and breastmilk exposure [68, 222]. Our previous review of data found 16 studies/reports [48, 49, 58, 82, 97, 110, 127, 128, 133, 248–254] of 336 pregnancies in which IVIG was used, mostly in APS or in the prevention of CHB in anti-Ro/La positive mothers. The studies identified were focused on therapeutic efficacy rather than the safety of IVIG; hence, all outcomes were confounded by use in patients with high-risk pregnancies and multiple concomitant medications. Overall, the number and type of maternal and foetal complications observed were compatible with known effects of the underlying maternal disease on pregnancy, rather than being specific to IVIG. The studies reviewed did not raise any new concerns to question the accepted safety of IVIG in pregnancy [1].

We identified two further studies of 67 exposures to IVIG to treat immune thrombocytopenia (ITP) in pregnancy [74, 79]. One study found that glucocorticoids increased the risk of maternal hypertension, while the addition of IVIG to corticosteroid regimes did not adversely affect pregnancy outcomes [79]. The other study found comparable benefits of IVIG compared with corticosteroids in treating ITP in pregnancy, compared with no treatment, and similar neonatal outcomes between the treatment groups [74]. UKTIS does not report on IVIG.

None of the studies we previously or recently identified addressed the use of IVIG in breastmilk exposure or with paternal exposure. LactMed states that immunoglobulin is a normal component of breastmilk, and data from two mothers indicate that IgG concentrations in milk are normal or higher, and IgM levels in milk are normal or lower, during IVIG therapy [192].

Recommendations for intravenous immunoglobulin in pregnancy and breastmilk exposure

i) IVIG is compatible with pregnancy (GRADE 1B, SOA 99.5%).
ii) IVIG is compatible with breastmilk exposure (GRADE 2C, SOA 100%).

Biologic DMARDs

Biological therapies are commonly used as second-line agents to treat various forms of IRDs. They are recombinant proteins, most commonly monoclonal IgG1 antibodies directed against specific targets, or fusion proteins containing the Fc portion of IgG1 joined to receptor-blocking proteins. The presence of the Fc region of IgG1 in most of these biologic drugs is required for their active placental transfer, which accelerates by active transport from the second trimester onwards. Biologic drugs are often given alongside other DMARDs, and decisions regarding continuation of treatment should be taken for each drug independently. Although the evidence base for biosimilar use in pregnancy and breastmilk exposure is more limited than for originator biologics, they would be expected to have comparable effects. Therefore, for pragmatic reasons, our recommendations are applicable to equivalent licensed biosimilars.

Five studies were identified that assessed the impact of biologic drugs as a whole on pregnancy outcomes [255–259]. These studies included a total of 379 pregnancies in women with autoimmune disease on predominantly anti-TNFα drugs, but also rituximab (RTX), abatacept (ABA), tocilizumab (TCZ), ustekinumab (UST) and anakinra. Separate birth outcomes for specific medications were not reported. Overall, the authors of these studies found no increased risk of miscarriage, stillbirth or congenital anomalies in biologic-exposed patients. One study that reported outcomes for 120 pregnancies in women with autoimmune diseases (predominantly RA and IBD) found a slightly increased risk of prematurity and a trend towards low birth weight in the biologic-exposed group compared with those not exposed [257]. However, once statistical modelling had been performed to correct for confounding by indication and proxies of unmeasured confounders, no association was found between biologic exposure and birth weight or gestational age. In addition, the same authors found that biologic use was not associated with an increased risk of serious infections in mothers, during postpartum, or in infants during the first year of life [256].

Anti-TNFα drugs

Five biologic agents that inhibit TNFα (TNFi) are currently licensed to treat IRDs: etanercept (ETA), infliximab (INF), adalimumab (ADA), golimumab (GOL) and certolizumab pegol (CZP). Three of these drugs (INF, ADA and GOL) are monoclonal IgG1 directed against TNFα, one (ETA) is a fusion protein of the TNF receptor joined to the Fc region of IgG1, while CZP is an antigen-binding fragment (Fab′) of a monoclonal anti-TNFα antibody which lacks the Fc region of IgG1 and has been conjugated with polyethylene glycol (PEG). These drugs have different half-lives, bioavailability and rates of placental transfer, which are relevant when considering their potential use in pregnancy.

Initial 2006/8 consensus recommendations advised avoidance of ETA, INF and ADA in pregnancy and breastfeeding due to a lack of evidence rather than evidence of harm [68, 222]. Previously, we reviewed outcome data from TNFi-exposed pregnancies ($n = 706$) of patients with predominantly IBD but also rheumatic disease and non-autoimmune-mediated recurrent spontaneous miscarriage, compared with ($n = 399$) disease and ($n = 170$) healthy control pregnancies [50, 52, 99, 100, 108, 109, 172, 173, 252, 260–279]. There were multiple confounders of concomitant therapies (including MTX, LEF

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

and MMF) and active inflammatory disease. Overall, these studies did not describe an increased incidence of adverse effects upon miscarriage rates, pregnancy duration, birth weight, foetal death or congenital malformation that was attributable to ETA, INF, ADA or CZP. At that time, there was limited information on placental transfer, and no published studies of GOL in human pregnancy or breastmilk exposure.

TNFi exposure in pregnancy and with breastmilk exposure has been extensively studied since our last search. We identified an additional 50 studies, reporting 12 491 pregnancy exposures to TNFi, including INF ($n \geq 5377$), ADA ($n \geq 2797$), ETA ($n \geq 2210$), CZP ($n \geq 776$) and GOL ($n \geq 196$) [37, 255–259, 280–323]. Many studies reported combined outcomes for exposure to different TNFi agents. The majority of studies of maternal exposure did not report an increased risk of preterm birth, miscarriage, low birth weight or congenital malformations [37, 255, 257–259, 280–286, 288–291, 294, 296, 298–302, 304–308, 314, 316–318, 320–323].

Different adverse outcomes were reported in some studies, however. A study of ETA found that the proportion of infants with major birth defects was higher (9.4% *vs* 3.5%, respectively) in ETA-exposed pregnancies ($n = 370$) than in pregnancies of disease-matched, non-exposed women ($n = 164$) [287]; however, the lack of a specific pattern of birth defects and the expected minimal placental transfer of ETA in early pregnancy did not support the biologic plausibility of a drug-related effect. A study reporting a lower live birth rate in INF-exposed pregnancies ($n = 99$) in women with Crohn's disease considered their findings to be confounded by more severe disease in those patients exposed to INF and increased exposure to other immunosuppressive agents [293]. A population-based study of TNFi-exposed pregnancies ($n = 1027$) found increased risks of preterm birth, caesarean section and SGA babies in comparison with TNFi-unexposed pregnancies ($n = 9399$) [295]; however, the authors noted that these associations may have been related to underlying disease activity rather than agent-specific effects, due to diverse findings across disease groups.

A retrospective cohort study of TNFi-exposed pregnancies ($n = 1457$) in women with IBD found TNFi exposure to be an independent risk factor for maternal complications and infections when compared with TNFi-unexposed pregnancies ($n = 9818$) [303]. In this study, TNFi exposure did not associate with congenital malformations or an increased risk of infection in children during the first year of life. Furthermore, there was no difference in the risk of complications in women exposed to TNFi during the third trimester, relative to cessation before week 24, although disease relapses were more common in those stopping TNFi prior to the third trimester. A study of 4961 pregnant women with autoimmune inflammatory conditions found similar risks of serious infections in women taking steroids, csDMARDs or TNFi during pregnancy, but found that higher doses of steroids were an independent risk factor for serious infections in pregnancy [323].

A registry-based study from Denmark and Sweden reported a non-statistically significant higher risk of having children with birth defects in women with RA, AS, psoriatic arthritis (PsA), IBD or psoriasis who had received TNFi during pregnancy ($n = 683$), relative to women with chronic inflammatory disease but without TNFi exposure ($n = 21\,549$) [310]; however, the heterogeneity of observed birth defects went against a common aetiology. A prospective cohort study of TNFi pregnancy exposures ($n = 495$) in women with chronic inflammatory disease (RA, AS, PsA, psoriasis and IBD) found prenatal TNFi exposure to be associated with an increased risk of birth defects without a distinct pattern of malformations, when compared with non-disease-matched, TNFi-unexposed controls ($n = 1532$) [312]. An increased risk of preterm births and reduced birth weight, but not spontaneous miscarriage, was also noted. The authors concluded that, although TNFi may carry a risk of adverse pregnancy outcomes of moderate clinical relevance, they may remain a treatment option, considering the impact of inadequately controlled disease on the mother and unborn child.

A small number of studies specifically compared risks between TNFi agents. In one study, INF was found to be associated with a greater risk for preterm births relative to ETA, and a higher prevalence of severely SGA babies relative to ETA and ADA, in pregnant women with RA, AS, PsA or psoriasis. In IBD, however, the risk of preterm births and SGA babies did not differ between INF and ADA [295]. In a study of individual safety reports in pregnant IBD patients exposed to TNFi ($n = 783$), the odds for maternal or foetal adverse events were found to be lower for CZP monotherapy, but not for INF or ADA monotherapy, when compared with an aminosalicylate monotherapy comparator in multi-level regression models [316]. In another study, the risk of birth defects did not differ significantly between ADA, INF or ETA-exposed women with chronic inflammatory diseases [310].

Several studies specifically compared outcomes for pregnancies exposed to TNFi during late *vs* early trimesters [37, 280–282, 284, 289, 291, 292, 295–297, 303, 305, 308, 309, 317], the majority of which reported no significant concerns with late trimester exposure. In a study of INF-exposed pregnancies ($n = 1850$) in women with IBD, RA, AS, PsA and psoriasis, frequencies of congenital abnormalities and other adverse birth and infant outcomes (including neonatal infections) were similar when comparing first and third trimester exposure [291]. In a study comparing early discontinuation of INF (>90 days before delivery; $n = 68$) to late discontinuation (<90 days before delivery; $n = 318$) in pregnancies of women with IBD, early discontinuation was associated with increased disease flares, more steroid usage and more preterm births than late discontinuation [292]. Rates of other adverse outcomes, including congenital malformations and infant respiratory infections, were similar between these groups. A further study of TNFi-exposed pregnancies ($n = 153$) in women with IBD reported that continuation of TNFi after gestational week 30, relative to cessation before week 30, was independently associated with modestly lower birth weights in multivariate regression models after adjustment for disease activity, but not other adverse infant outcomes [297].

Different rates of placental transfer of TNFi and timing of drug exposure in the second and/or third trimester of pregnancy influenced previous advice regarding avoidance of live vaccines in the first 7 months of life. Previously, a small cohort study found CZP (a PEGylated Fab' fragment, lacking the Fc region) to have minimal rates of placental transfer compared with INF and ADA [270], and two case reports demonstrated very low rates of placental transfer of ETA administered throughout pregnancy [108, 274]. Therefore, previous recommendations described discontinuation of ADA and ETA at the end of the second trimester to ensure negligible or no drug is detectable in cord blood at delivery. For INF, due to its prolonged bioavailability and higher rate of placental transfer, it

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

was recommended to be stopped earlier in pregnancy (at 16 weeks) for it to be undetectable in cord blood at delivery.

Since the last guideline, we found increased data demonstrating different rates of placental transfer of TNFi [283, 285, 302, 308, 309]. In a study of pregnant women with IBD exposed to INF ($n = 44$) or ADA ($n = 36$), the median time to drug clearance was 4 months for ADA and 7 months for INF [308]. In this study, continuation of TNFi in the third trimester did not increase the risk of childhood infection, relative to discontinuation before the third trimester. In a prospective study of ADA ($n = 58$) and INF-exposed pregnancies ($n = 73$) in women with IBD, cord blood samples showed significantly higher levels of INF than ADA at birth [302]. In this study, placental transfer of INF increased exponentially over the third trimester, while ADA transportation was limited and increased in a linear fashion. Maternal and birth outcomes were comparable between these groups, as were one-year infant health outcomes, including infection and adverse reactions to vaccinations. A study of infants ($n = 14$) with third trimester maternal exposure to CZP found minimal rates of placental transfer, supporting continuation of this treatment during pregnancy [283]. Recent data, published after our literature search and highlighted by UCB Pharma during public consultation, reported no signal for adverse pregnancy outcomes following maternal CZP exposure in a large ($n = 1425$) cohort [324].

UKTIS reports that studies that investigate the use of TNFi (ADA, CZP, ETA and INF only) during pregnancy have not found an overall increased risk of congenital malformation for these therapies as a class; there is also no compelling evidence of an increased risk for spontaneous miscarriage, intrauterine death or adverse neurodevelopmental outcomes; however, data are currently too limited to exclude adverse effects on the foetus. LBW and preterm birth have been associated with *in-utero* TNFi exposure in some studies but are confounded by maternal disease. UKTIS also states that there are theoretical concerns that the use of immunosuppressant antibodies, which actively cross the placenta, may result in neonatal or infant immunosuppression and increase the risk of infection; therefore, a delay is advised in administration of live vaccines to infants of: 5 months after last dose of ADA; 16 weeks after last dose of ETA; and until 6 months of age after *in-utero* INF. In contrast, as CZP is minimally transferred across the placenta, it is unlikely that infants born to women who used CZP in pregnancy would experience sufficient levels of TNFα inhibition to significantly inhibit their immune response [171].

Previously, we found case reports and case series reporting detection of ADA in breastmilk but not in infant serum [269], and detection of ETA and INF in breastmilk in some [108, 267, 273, 274] but not all studies [265], with no adverse effects detectable in any of these breastfed infants. We found nine additional studies of TNFi reporting on 133 breastmilk exposures [283, 285, 300, 307, 308, 317, 319, 325, 326]. Overall, these studies did not find any adverse effects of TNFi. A study of mothers ($n = 17$) breastfeeding while taking CZP found minimal transfer of this drug into breastmilk [325]. Another study reported low or undetectable concentrations of INF, ADA, CZP, GOL and UST in 72 breastmilk samples [326]. In this study, breastfed infants on biologics ($n = 243$), thiopurines ($n = 102$) or combination therapy ($n = 67$) were found to have similar risks of infection and rates of milestone achievement compared with infants unexposed to these drugs via breastmilk or not breastfed. LactMed states that: CZP is excreted into breastmilk in some, but not all, women in small amounts; INF is usually either not detectable in breastmilk or detectable at very low levels; ETA, ADA and GOL are minimally excreted into breastmilk, with all TNFi being predicted to be poorly absorbed by the infant due to large molecular weight of each drug [192]. While some evidence suggests that IgG antibodies may not be digested by the gut in the early neonatal period [327, 328], other studies demonstrate marked digestion of IgG by the infant gut [329, 330].

Previously, we found long-term follow-up data in children exposed *in utero* to ETA [108, 266, 270, 272–274], ADA [269] and CZP [270]. We found an additional 16 studies reporting long-term follow-up data after exposure to TNFi [256, 291, 292, 299–303, 307–309, 317, 319–322]. In one study, 196 children with intrauterine exposure to TNFi (ADA, $n = 81$; INF, $n = 115$) for maternal IBD were followed up for 5 years, finding no association with long-term adverse health outcomes (including childhood infections and vaccination adverse reactions) when compared with TNFi-unexposed controls [296]. This study included women continuing TNFi during the third trimester, where no increased risk of infection was noted in their offspring. In a retrospective cohort study of children ($n = 388$) exposed to TNFi (ADA, $n = 164$; INF, $n = 223$; CZP, $n = 1$) *in utero* for maternal IBD, the incidence of severe infections was similar to TNFi-unexposed children of IBD mothers after median follow-up of 5 years [301]. Similarly, in another study, the risk of serious or opportunistic infections during the first year of life in live-born infants ($n = 229$) exposed to ADA during pregnancy in women with RA or IBD was not significantly different to disease-matched, non-exposed controls and healthy controls [281]. In this study, the risk of infection remained similar when restricting to infants exposed to ADA during the third trimester. Two additional studies, which were not included in our final analysis because they did not report primarily on pregnancy or breastmilk exposure outcomes, described infections in the first 3 years of life in children after *in-utero* exposure to TNFi (predominantly ETA, ADA and INF) and/or csDMARDs for IRDs, psoriasis and IBD. One study of 493 children exposed *in utero* to TNFi reported an increased risk of some site-specific infections but not other adverse outcomes within the first year of life only [331]. The other study of 1027 children demonstrated a slightly increased risk of paediatric infections associated with both TNFi and csDMARDs in the first and second year after birth; however, the authors noted that this association was present regardless of third trimester exposure and could also have been confounded by disease severity [332].

Studies of vaccine safety and efficacy were not specifically sought through our systematic literature search but are relevant to consider, because most guidance recommends avoidance of live vaccines up to 6–12 months post-partum in infants exposed to bDMARDs in the second/third trimester [1, 333]. This advice is heavily influenced by the finding that placental transfer of bDMARDs can lead to persistence of drug levels by up to 12 months following *in-utero* exposure, with a median clearance time of 6 months and longest clearance times for INF. In addition, a fatal case of disseminated TB-like disease had been reported in a 4-month-old infant who had received Bacille Calmette et Guerin (BCG) vaccination following *in-utero* exposure to INF [334]. This guidance

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

impacts on rotavirus vaccination and, if indicated, the BCG vaccine, while the measles, mumps and rubella (MMR) vaccine (typically given at 12 months) is not affected. These restrictions significantly impact on rotavirus only, since the BCG vaccine may easily be deferred to be given later in life, while the rotavirus course of vaccination must be completed by 24 weeks of age due to risk of intussusception [335]. Currently, the restrictions may be avoided by discontinuing TNFi in the second or early third trimester, several half-lives prior to delivery.

Rotavirus continues to be a major cause of acute gastroenteritis in young children and has been estimated to result in >500 000 deaths and 2.4 million hospital admissions worldwide [336]. The rotavirus vaccine is over 85% effective at protecting against severe rotavirus gastroenteritis in the first two years of life [335]. Although current UK guidance recommends avoidance of rotavirus vaccination in infants of mothers exposed to biologics during pregnancy [337], it refers readers to the green book [335]. This text states that, although the vaccine is a live attenuated virus, with the exception of severe combined immunodeficiency (SCID), the benefit from vaccination may exceed risk in other forms of immunosuppression [335].

There are increasing reports of the safe use of rotavirus vaccination in infants following perinatal exposure to bDMARDs, including INF. A systematic review described cohort studies and case reports of infants ($n = 54$) of mothers who received antenatal bDMARDs (mostly TNFi, including INF) who then received rotavirus vaccine without significant adverse effects [336]. The authors of that review recommended that otherwise healthy newborns with a history of perinatal exposure to bDMARDS should receive rotavirus vaccinations as per the recommended schedule, while the BCG vaccine should be withheld in the first year of life. Not all consensus review articles have reached the same conclusion, however, with some recommending avoidance of both rotavirus and BCG vaccinations in infants exposed to bDMARDs *in utero* in the first 6 months of life unless levels of biological drugs are undetectable [338], or avoidance of live vaccines until 6–12 months of age in infants exposed to biologics that may cross the placenta at clinically significant levels [339].

A systematic review published in abstract form after our search date evaluated vaccine safety in infants exposed to bDMARDs or tsDMARDs in pregnancy [340]. It identified *in-utero* exposures to ADA ($n = 326$), CZP ($n = 18$), ETA ($n = 1$), INF ($n = 408$), GOL ($n = 1$), RTX ($n = 1$), TCZ ($n = 3$), UST ($n = 1$) and no tsDMARD exposures in mostly IBD ($n = 849$) pregnancies. Infant vaccination included: BCG ($n = 111$) and/or rotavirus ($n = 48$) in the first year of life (many <6 months); and MMR at 12 months ($n = 590$), 6–9 months ($n = 12$) and at 1, 2 or 4 months ($n = 3$). Adverse events with BCG vaccination included one death, two large local skin reactions, and one infant with axillary lymphadenopathy. A freedom of information request to the MHRA revealed four further suspected fatal BCG infections in infants exposed to TNFi *in utero* (INF, $n = 2$; ADA, $n = 1$; and unspecified TNFi, $n = 1$). Adverse effects noted in infants given rotavirus vaccination were mild and at similar frequency to those in biologic-unexposed infants. No complications were reported with MMR vaccination. Overall, the most evidence of clinically harmful effects was found after administration of BCG to infants <3 months of age and after *in-utero* exposure to INF. In contrast, outcomes following rotavirus (mostly <6 months) and MMR (mostly at a year) vaccinations were reassuring. Notably, disseminated rotavirus infection has not been reported.

Other systematic reviews have also evaluated vaccine efficacy, and report adequate vaccination response (measured by antibody levels) following non-live vaccination in infants exposed to TNFi [336], although there are conflicting reports, with low antibody responses to the Haemophilus influenzae type-B vaccine reported in some infants exposed to INF or ADA [338].

Although our literature search did not assess evidence relating to the peri-operative use of TNFi or other bDMARDs (for example, in the context of caesarean sections), relevant guidance can be found in other BSR guidelines [341].

Recommendations for anti-TNFα medications in pregnancy and breastmilk exposure

i) Women with no/low disease activity established on a TNFi with known placental transfer (INF, ADA, GOL) do not need to be switched to an alternative TNFi with established minimal placental transfer (CZP) either before or during pregnancy (GRADE 1B, SOA 100%).
ii) CZP is compatible with all three trimesters of pregnancy, has no to minimal placental transfer compared with other TNFi, and does not require any alteration to the infant vaccination schedule (GRADE 1B, SOA 100%).
iii) Women considered to have low risk of disease flare on withdrawal of TNFi in pregnancy could stop INF at 20 weeks, ADA and GOL at 28 weeks, and ETA at 32 weeks so that a full-term infant can have a normal vaccination schedule, with rotavirus vaccination at 8 weeks as per the UK schedule (GRADE 1B, SOA 99.5%).
iv) INF, ADA, ETA or GOL may be continued throughout pregnancy to maintain maternal disease control; in these circumstances, live vaccines should be avoided in infants until they are 6 months of age (GRADE 1B, SOA 100%).
v) If a TNFi is stopped in pregnancy, it can be restarted as soon as practical post-partum in the absence of infections or surgical complications, regardless of breastfeeding status, to ensure control of maternal disease (GRADE 1C, SOA 100%).
vi) TNFi are compatible with breastmilk exposure (GRADE 1C, SOA 100%).

Other biologic DMARDs (non-TNFi)

Data relating to non-TNFi biologic use in pregnancy remain scarce, and in this guideline updated case reports and small case series were excluded for consistency. A recent systematic review summarized all available data (including case reports) on non-TNFi bDMARDs and tsDMARDs and did not identify any adverse safety signals [342].

Rituximab

Previously, we found insufficient evidence to be confident that RTX is compatible with pregnancy and recommended it should be stopped 6 months before conception, although there were no direct reports of teratogenicity and only second/third trimester exposure was associated with neonatal B-cell

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

depletion. RTX is a monoclonal IgG1 that actively crosses the placenta from 16 weeks of pregnancy onwards. Previously, we found eight studies [50, 343–349] on 173 RTX-exposed pregnancies that met our inclusion criteria. Overall, these studies reported reassuring pregnancy outcomes, but found low B cells at birth in infants exposed to RTX in the second/third trimester, no human breastmilk exposure studies were identified [1].

We identified five further studies of 143 RTX pregnancy exposures [350–354] in addition to eight exposures in studies that reported on combined outcomes of multiple biologic-exposed pregnancies (see 'Biologic DMARDs' above). Four studies ($n = 135$) of mostly pre-conception or first trimester maternal exposure did not report an increased risk of preterm birth, miscarriage, LBW or congenital anomaly [350–352, 354]. An additional cohort study of eight mothers treated with one to four cycles of RTX during pregnancy ($n = 6$ for diffuse large B-cell lymphoma; $n = 2$ for SLE) found a high rate of preterm birth and intrauterine infections, but noted the potential for confounding by the underlying disease and concomitant medications [353].

UKTIS reports that there is insufficient evidence to assess whether the risk for spontaneous miscarriage, congenital malformation, birth weight, intrauterine death or adverse neurodevelopmental outcomes is increased following exposure to RTX *in utero*. Due to a lack of data on the effects of RTX on the neonatal/infant immune system, it recommends delaying administration of live vaccines following *in-utero* exposure to RTX, although no specific timescale is given [171].

There were three studies of breastmilk exposure ($n = 23$) to RTX [352, 354, 355]. One study detected minimal transfer of RTX into the breastmilk of nine breastfeeding mothers, with a relative infant dose of rituximab well below theoretically acceptable levels (<0.4%) [355]. No adverse effects attributable to RTX exposure were reported in the breastfed infants, and the drug was considered to have an acceptable benefit-to-risk ratio, supporting both maternal treatment and breastmilk exposure. LactMed states that the amount of RTX in breastmilk is very low and absorption is unlikely because it is a protein with a high molecular weight that is likely to be partially destroyed in the infant's gastrointestinal tract; thus, absorption by the infant is probably minimal [192].

Vaccine efficacy after prenatal exposure to RTX is much less studied, and systematic reviews have identified adequate non-live vaccination outcomes from 5/6 RTX-exposed infants, with low immunity to diphtheria detected in one 11-month-old infant exposed to RTX at conception [336, 338].

Recommendations for rituximab in pregnancy and breastmilk exposure

i) Limited evidence has not shown RTX to be teratogenic; however, there remains insufficient evidence to be confident that it is compatible with pregnancy. Consider stopping the drug at conception (GRADE 2C, SOA 99.3%).
ii) RTX may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 99.7%).
iii) If RTX is used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 98.7%).
iv) Based on limited evidence, maternal treatment with RTX is compatible with breastmilk exposure (GRADE 2C, SOA 99.5%).

Interleukin-6 inhibitors

Tocilizumab

Due to insufficient data, we previously recommended that TCZ be stopped at least three months pre-conception, but that unintentional exposure early in the first trimester is unlikely to be harmful due to its IgG1 structure. This limited data came from outcomes of 33 pregnancies in 32 patients, published in abstract form [356]. We identified three further studies of 365 pregnancy exposures to TCZ [357–359] in addition to four exposures in the papers described above which reported combined outcomes of multiple biologic-exposed pregnancies (see 'DMARDs' above). These studies of mainly first trimester exposure did not find increased rates of congenital abnormalities in patients with rheumatic disease. Two studies commented on a higher than background rate of spontaneous miscarriage [357, 359], and could not exclude an effect on birth weight and risk of prematurity, while acknowledging potential confounding factors. For example, stopping effective treatment early in pregnancy could destabilize the rheumatic disease, with adverse consequences for the pregnancy.

UKTIS notes a small number of studies lacking comparator groups that are confounded by maternal disease, and states that there is currently no compelling evidence that TCZ is teratogenic or fetotoxic. Due to lack of data on effects on the neonatal/infant immune system, it recommends that live vaccines are avoided until the infant is 6 months of age [171].

One study of $n = 2$ breastmilk exposure to TCZ did not report any adverse effects attributable to the drug [360]. Saito *et al.* have described a total of four cases of babies exposed to TCZ via breastmilk with no complications in the infants (three publications which did not meet our inclusion criteria) [360–362]. Concentrations of TCZ were measured in the breastmilk in these studies and two additional cases reports, with no clinical adverse effects reported [363, 364]. Levels in the breastmilk were found to peak on day three following the infusion [362], but were significantly lower than the corresponding maternal serum concentrations in all of these cases, ranging from 11% in colostrum [364], down to as low as 1:2000 [360, 363].

Sarilumab

No papers were found that met our inclusion criteria. Sanofi provided data on 13 patients who became pregnant in the sarilumab and DMARD long-term safety population, of whom seven had a miscarriage [365]. In addition, two male patients fathered two healthy children.

Recommendations for IL-6 inhibitors in pregnancy and breastmilk exposure

i) Limited evidence has not shown IL-6 inhibitors (IL-6i) to be teratogenic; however, there remains insufficient evidence to be confident that they are compatible with pregnancy. Consider stopping the drug at conception. Any exposure, however, during pregnancy is unlikely to be harmful (GRADE 2C, SOA 99.7%).
ii) IL-6i may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 100%).

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

iii) If IL-6i are used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 99.3%).
iv) Based on limited evidence, maternal treatment with IL-6i is compatible with breastmilk exposure (GRADE 2C, SOA 100%).

Interleukin-1 inhibitors

Anakinra

Anakinra is a recombinant form of human interleukin-1 receptor antagonist (IL-1Ra) with a high molecular weight which was not found to cross *ex-vivo* full-term human placentae [366]. Previously, there was insufficient information evidence on which to base a recommendation for anakinra in pregnancy, but unintentional exposure in the first trimester was considered unlikely to be harmful [1]. This limited evidence came from reports on five pregnancies in three studies/reports, with no evidence of harm [50, 367, 368].

Subsequently, we identified four studies of 43 pregnancy exposures to anakinra [369–372], in addition to one exposure in the papers described above which reported combined outcomes of multiple biologic-exposed pregnancies (see 'Biologic DMARDs' above). These exposures were mostly in patients with periodic fevers and severe maternal disease. Overall, outcomes were reassuring, although two congenital renal anomalies and two cases of oligohydramnios (which can be linked to foetal renal anomalies) were reported [369, 371, 372]. It was unclear, however, whether the renal abnormalities were associated with antenatal anakinra use or maternal hyperthermia or both. Given the significant beneficial effects of anakinra in suppressing maternal disease with limited pregnancy-compatible options, it was considered a safe alternative in managing disease in women with periodic fever in pregnancy. UKTIS does not report on anakinra.

Two studies of $n = 12$ breastmilk exposures to anakinra did not report any adverse effects attributable to the drug [369, 371]. LactMed states that IL-1Ra is a normal component of human milk, possibly as an anti-inflammatory agent, and that several infants have been breastfed during maternal anakinra therapy with no obvious adverse effects. If anakinra is required by the mother, it is not a reason to discontinue breastfeeding [192].

Canakinumab

Canakinumab is a human monoclonal antibody to IL-1. There is, therefore, the potential for active transport across the placenta from the second trimester onwards.

One paper reporting canakinumab use from pre-conception in eight pregnancies (stopped during first trimester in 5/8 pregnancies) met our inclusion criteria [369]. There were seven live births, all of whom were healthy, full term and normal birth weight. One mother with refractory Cogan syndrome had an early miscarriage at 6 weeks (after a miscarriage the previous year while on anakinra).

In addition, Novartis supplied information from analyses of the Novartis Global Safety Database, which included 76 maternal and nine paternal exposures [373]. There were 47 known pregnancy outcomes, with 27 healthy newborns, one preterm birth (with meconium staining not thought likely to be related to canakinumab exposure), nine spontaneous miscarriages (including two miscarriages related to paternal exposure in one father) and three elective terminations. Seven other adverse events were reported: one case of congenital pyelocaliectasis following paternal exposure to canakinumab; one case of congenital musculoskeletal abnormality following maternal exposure, with insufficient data on other contributory factors; one case of inherited genetic disease with neonatal RSV infection and pyrexia following infant vaccinations; and four adverse events very unlikely to relate to canakinumab exposure (one newborn non-serious hypotension and three cases of likely inherited disease: Muckle–Wells syndrome and CAPS).

One cohort study reported breastmilk exposure in four infants whose mothers were prescribed regular canakinumab, with no reported serious infections or developmental abnormalities [369].

Recommendations for IL-1 inhibitors in pregnancy and breastmilk exposure

i) Limited evidence has not shown IL-1 inhibitors (IL-1i) to be teratogenic; however, there remains insufficient evidence to be confident that they are compatible with pregnancy. Consider stopping the drug at conception. Any exposure, however, during pregnancy is unlikely to be harmful (GRADE 2C, SOA 99.8%).
ii) IL-1i may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 100%).
iii) If IL-1i are used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 99.3%).
iv) Based on limited evidence, maternal treatment with IL-1i is compatible with breastmilk exposure (GRADE 2C, SOA 100%).

Abatacept

ABA is a fusion protein containing the Fc region of IgG1 fused to the extracellular domain of CTLA-4; therefore, it is able to cross the placental barrier from approximately week 16. Previously, there was insufficient data to recommend ABA in pregnancy, but unintentional exposure early in the first trimester was considered unlikely to be harmful [1]. This conclusion was based on reports from 11 pregnancy exposures (and a further eight exposures reported in abstract form only), many of which were confounded by concomitant MTX [175, 349, 374].

We identified two further studies of at least 196 pregnancy exposures to ABA (with some overlap of data) [375, 376], in addition to three exposures in the papers described above which reported combined outcomes of multiple biologic-exposed pregnancies (see 'Biologic DMARDs' above). The data from these studies did not suggest an increased risk of adverse pregnancy outcomes with ABA, and many of the congenital abnormalities were considered by the authors to be associated with concomitant use of other teratogenic DMARDs. The apparently high rate of spontaneous miscarriage (total $\geq$48/184) is difficult to interpret due to confounding by indication and other medications such as MTX, as well as detection bias of early miscarriages during the close monitoring of clinical trials [375]. The authors concluded that ABA should only be used during pregnancy if the benefit to the mother justifies potential risk to the foetus. UKTIS does not report on ABA.

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

Although it did not meet our inclusion criteria, we identified one case report of breastmilk exposure to ABA, with no adverse effects, in which ABA was secreted into breastmilk at levels 1/200–1/300 of those in serum [377]. LactMed describes one case report that reported concentrations of ABA in milk were very low and did not appear to affect the breastfed infant, concluding that if ABA is required by the mother, it is not a reason to discontinue breastfeeding, although alternative drugs may be preferred [192].

Recommendations for abatacept in pregnancy and breastmilk exposure

i) Limited evidence has not shown ABA to be teratogenic; however, there remains insufficient evidence to be confident that it is compatible with pregnancy. Consider stopping the drug at conception. Any exposure, however, during pregnancy is unlikely to be harmful (GRADE 2C, SOA 99.3%).
ii) ABA may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 99.3%).
iii) If ABA is used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 99.3%).
iv) Based on limited evidence, maternal treatment with ABA is compatible with breastmilk exposure (GRADE 2C, SOA 99.5%).

Belimumab

Belimumab (BEL) is a fully humanized monoclonal IgG1 that inhibits B-cell activating factor. Previously, our systematic search did not identify any publications that met our search criteria on use of BEL in human pregnancy, although we found reference to pregnancy outcomes from placebo-controlled, phase 2 and 3 studies in 83 SLE pregnancies [378], and BEL pregnancy registry data describing known outcomes from 118 SLE pregnancies [379]. Overall, these studies did not identify any pattern of adverse effects in pregnancy directly attributable to BEL.

We subsequently identified one study of 66 BEL pregnancy exposures [380]. Total foetal losses in BEL-treated subjects were similar to background estimates in SLE patients (~25%), although data remain limited. Another six studies, which did not meet our search criteria [381–386], reported an additional 124 pregnancies exposed to BEL. There was only one reported congenital abnormality: a case report of mild Ebstein's anomaly in a baby following successful control of SLE (with previous lupus nephritis and APS, previously only controlled on MMF) [381]. Two case series (26 pregnancy exposures) reported preterm delivery in 12/22 live births, with six babies being SGA [385, 386]. However, these cohorts included patients with complex rheumatic disease (SLE and APS), including some patients with previous lupus nephritis and active disease at conception [385], and a high average maternal age and rate of previous pregnancy losses [386]. Both authors concluded that, while careful consideration and further research is required, BEL could be a reasonable treatment option for patients with SLE requiring treatment in pregnancy. UKTIS does not report on BEL.

Although they did not meet our inclusion criteria, we identified two cases of breastmilk exposure while on BEL [381, 382]. No neonatal outcomes, adverse or otherwise, were reported in one case [381]. In the other case, there were no adverse effects, and BEL was secreted into breastmilk at levels 1/200–1/500 of those in serum [382]. LactMed states that, based on preliminary information that BEL levels in breastmilk are very low and infant absorption is probably minimal, if BEL is required by the mother, it is not a reason to discontinue breastfeeding, although caution is required, especially while nursing a newborn or preterm infant [192].

Recommendations for belimumab in pregnancy and breastmilk exposure

i) Limited evidence has not shown BEL to be teratogenic; however, there remains insufficient evidence to be confident that it is compatible with pregnancy. Consider stopping the drug at conception. Any exposure, however, during pregnancy is unlikely to be harmful (GRADE 2C, SOA 99.3%).
ii) BEL may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 99.5%).
iii) If BEL is used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 98.8%).
iv) Based on limited evidence, maternal treatment with BEL is compatible with breastmilk exposure (GRADE 2C, SOA 99.5%).

Interleukin-17 inhibitors

Interleukin-17 inhibitors (IL-17i) were not in general use and so not considered in our previous search. Secukinumab has an IgG1 structure, which may theoretically suggest increased transplacental transfer compared with the IgG4 structure of ixekizumab.

We found three studies of mostly first trimester pregnancy exposures to secukinumab ($n = 244$) and ixekizumab ($n = 18$) [387–389]. The authors did not report any increased incidence of adverse outcomes directly attributable to the drugs, although information, particularly for ixekizumab, remains very limited.

In addition, Novartis provided data from a search of their Global Safety Database, relating to 298 reports of maternal pregnancy exposures and 90 paternal exposures to secukinumab, mostly during the first trimester [390]. No outcome data were provided, but analysis within Novartis did not reveal any new safety information. UKTIS does not report on these drugs.

There were no data on breastmilk exposure to IL-17i identified in our search or in LactMed. Data provided from the Novartis Global Safety Database identified six breastmilk exposures to secukinumab, including one report of newborn pyrexia during breastfeeding [390]. The data in all cases were too limited to draw conclusions, but no new safety concerns were inferred.

Recommendations for interleukin-17 inhibitors in pregnancy and breastmilk exposure

i) Limited evidence has not shown IL-17i to be teratogenic; however, there remains insufficient evidence to be confident that they are compatible with pregnancy.

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

Consider stopping the drug at conception. Any exposure, however, during pregnancy is unlikely to be harmful (GRADE 2C, SOA 99.3%).

ii) IL-17i may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 99%).

iii) If IL-17i are used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 99.3%).

iv) Based on limited evidence, maternal treatment with IL-17i is compatible with breastmilk exposure (GRADE 2C, SOA 99.5%).

Interleukin-12/23 inhibitors

UST is an interleukin-12/23 inhibitor (IL-12/23i) with an IgG1 structure. UST was not in general use and not considered in our previous search. We found three studies of mostly first and second trimester pregnancy exposures to UST ($n = 517$) for maternal psoriasis, PsA and IBD [391–393]. Overall, these data showed that the rates of live births, spontaneous miscarriages and congenital anomalies were consistent with the general population and TNFi-exposed pregnancies.

Similarly, UKTIS did not identify any specific drug-related risk but was unable to provide a reliable evidence-based evaluation of risk due to limited information [171].

Although they did not meet our inclusion criteria, we identified two reports of exposure to UST during breastmilk exposure [326, 394]. In one case report, the trough level of UST in breastmilk after restarting this drug post-partum in a Crohn's disease patient was initially in the same range as the corresponding serum trough level, and then decreased during maintenance therapy [394]. In another study assessing breastfeeding mothers taking a range of biologic medication for IBD, UST was detected at low levels in 4/6 mothers taking this medication [326]. Overall, in this study, breastfed infants of mothers on biologics were found to have similar risks of infection and rates of milestone achievement compared with non-breastfed infants or infants unexposed to these drugs. LactMed states that UST is either not detectable or found at very low levels in breastmilk and infant absorption is probably minimal; as such, if UST is required by the mother, it is not a reason to discontinue breastfeeding, although caution is required especially while nursing a newborn or preterm infant [192].

Recommendations for interleukin-12/23 inhibitors in pregnancy and breastmilk exposure

i) Limited evidence has not shown UST to be teratogenic; however, there remains insufficient evidence to be confident that it is compatible with pregnancy. Consider stopping the drug at conception. Any exposure, however, during pregnancy is unlikely to be harmful (GRADE 2C, SOA 99.3%).

ii) UST may be considered to manage severe maternal disease in pregnancy if no other pregnancy-compatible drugs are suitable (GRADE 2C, SOA 98.8%).

iii) If UST is used to treat severe maternal disease in the third trimester, it is currently recommended to avoid all live vaccines in the infant vaccination schedule until 6 months of age (GRADE 2C, SOA 99.3%).

iv) Based on limited evidence, maternal treatment with UST is compatible with breastmilk exposure (GRADE 2C, SOA 99.5%).

Anifrolumab

Anifrolumab is a fully human, IgG1κ monoclonal antibody to type I interferon receptor subunit 1. Although it is not currently licensed for use in the UK, anifrolumab is approved for use in other countries, including FDA approval to treat moderate-to-severe SLE in the USA [395]. Although there is no published evidence on the use of this drug in pregnancy, breastmilk or paternal exposure, further information was provided by AstraZeneca on data from completed trials. Despite the mandatory contraception use in anifrolumab clinical trials, pregnancies have been reported in 20 SLE patients receiving anifrolumab in studies completed by December 2021. Patients who became pregnant during studies had to immediately discontinue the investigational product. No anifrolumab-associated congenital abnormalities or anifrolumab-associated adverse events have been observed in the clinical trials. Current data on anifrolumab pregnancy exposure are insufficient to inform about potential drug-related risks and therefore post-authorisation pregnancy studies are planned.

UKTIS does not report on anifrolumab. Although there is no information regarding breastmilk exposure to anifrolumab, LactMed states that due to its large molecular weight, the amount in milk is likely to be very low, and it is also likely to be partially destroyed in the infant's gastrointestinal tract with minimal absorption by the infant [192]. Based on this limited evidence, we have not made any recommendations on this drug.

Targeted synthetic DMARDs

Data relating to tsDMARD use in pregnancy remain scarce, and in this guideline, updated case reports and small case series were excluded for consistency. A recent systematic review summarized all available data including case reports and raised no additional safety concerns [342]. No studies were found relating to apremilast use in pregnancy, and therefore we were unable to make any recommendations.

JAK inhibitors

Tofacitinib (TOF), baricitinib (BAR) and upadacitinib (UPA) are oral Janus kinase inhibitors (JAKi) which were not in general use and so not considered in our previous search. They are small molecule inhibitors of low molecular weight which could theoretically cross the placenta.

JAKi have a short half-life (~3 h for TOF), although biological changes can persist for longer (for example, dose-dependent reductions in NK cells and CRP do not appear to reverse before 2 weeks after discontinuation) [396].

We identified three published reports of pregnancies during RCTs and post-marketing surveillance reports for TOF, but due to probable overlap, only the later 2018 paper was included (further updates were published in abstract form in 2020) [397–399]. This included 116 pregnancy exposures to TOF, with the known reported outcomes including 15/72 first trimester miscarriages, and major malformations in 2/44 live births (one pulmonary valve stenosis and one ventricular septal defect), which was in line with background risks in the general population [397].

Pfizer medical information supplied further details on pregnancies reported during the TOF clinical trials programmes

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

[400]. The RA and psoriasis trials included a total of 60 maternal exposures during the first trimester with 51 known outcomes, with concomitant MTX use either before or during pregnancy in at least 19 of these cases [399]. There were 28 healthy newborns, two premature infants, and one congenital malformation where the mother was also taking losartan. In these trials, there were nine spontaneous miscarriages, nine medical terminations, and one elective termination. In the ulcerative colitis (UC) clinical trial programmes, there were 15 maternal exposures with 13 known outcomes (nine healthy newborns, two spontaneous miscarriages and two medical terminations) [397, 398]. In the PsA programmes, there were a further four maternal and three paternal exposures with six known outcomes (three healthy newborns, two spontaneous miscarriages and one medical termination) [397]. Post-marketing reports up to 2017 were included in the analysis by Mahadevan *et al.* with 42 (predominantly first trimester) maternal exposures and three paternal exposures, with only 12 known outcomes (seven healthy newborns, one congenital malformation, three spontaneous miscarriages and one medical termination) [397].

Although not eligible for inclusion, we found one case report of an RA pregnancy exposed to BAR from pre-conception up to 17 weeks gestation, with a healthy infant delivered at 38 weeks gestation by caesarean section [401]. In addition, Eli Lilly provided data on 36 maternal pregnancies during the BAR clinical trials programme, with 25 known outcomes (trimester and duration unspecified) [402]. Many were taking concomitant medications, including MTX ($n = 14$). Outcomes included 13 healthy newborns (including three born preterm), seven spontaneous miscarriages (with MTX exposure in six of these), and five elective terminations. In addition, there have been 22 post-marketing reports of pregnancy exposures to BAR, with four known outcomes as of January 2021, including three healthy newborns (including one preterm), and one spontaneous miscarriage at 13 weeks in a 36-year-old mother (early first trimester exposure to BAR with concomitant medications for RA including HCQ, GOL, prednisolone, MTX, folic acid and ibuprofen) [402].

UKTIS does not reported on JAKi. We found no evidence relating to breastmilk exposure to JAKi. Given that they are small molecules and likely to transfer into breastmilk, they should be avoided. LactMed states that no information is available on the use of TOF or BAR during breastmilk exposure, and alternate drugs are preferred, especially while nursing a newborn or preterm infant [192].

There were no studies identified that met our inclusion criteria for UPA. Data provided by AbbVie included 54 maternal pregnancies inadvertently exposed to UPA in the month prior to conception or during the first trimester of pregnancy during the clinical trials programme [403]. The 41 known outcomes included 17 healthy live births (including two premature deliveries), 14 spontaneous miscarriages (10 of whom were on concomitant MTX), nine elective terminations (all with no reported foetal defects) and one ectopic pregnancy. Filgotinib was NICE-approved after our search window, and so was not included in our search.

Recommendations for JAK inhibitors in pregnancy and breastmilk exposure

i) There are insufficient data to make a recommendation on JAKi use during pregnancy and they should be stopped at least two weeks before planned conception (GRADE 2C, SOA 99.5%).
ii) There are insufficient data to recommend JAKi in breastfeeding and, given they are likely to transfer into breastmilk, they should be avoided (GRADE 2C, SOA 99.5%).

Paternal exposure

Hydroxychloroquine

For HCQ, no additional paternal exposures were identified to the previously identified cohort study [52] and case series [404] of 13 pregnancies after paternal exposure to HCQ, which did not find any increased risk of adverse foetal outcomes.

Corticosteroids

Previously, four cohort studies [52, 405–407] and two case series [404, 408] reported on outcomes from ≥2127 pregnancies after paternal exposure to prednisolone, and a case-control study [409] and a case series [410] reported on outcomes from ($n = 4$) pregnancies after paternal exposure to methylprednisolone. Overall, the quality of these studies was low, but reassuringly they did not identify an increased risk of adverse foetal outcomes. Since then, an additional study of 2380 paternal exposures to corticosteroids did not identify any statistically significant increase in adverse birth outcomes [411].

Methotrexate

Previous low-quality evidence from outcomes of pregnancies after paternal exposure ($n = 263$) to predominantly low-dose MTX did not find any adverse effects [1]. We identified an additional six studies of paternal exposures to MTX ($n = 2026$) within three months of conception that similarly found no increased risk of adverse foetal outcomes when compared with MTX-unexposed controls ($n = 4\,700\,599$) [184–189]. An additional study examined foetal outcomes with paternal MTX (and other DMARD) use compared with abatacept; however, outcomes for individual drugs were not reported [375].

Sulfasalazine

Our previous review of three cohort [52, 407, 412] and one case-control study [409] reporting on 237 pregnancies after paternal exposure to SSZ did not find an increased risk of adverse foetal outcomes, although the quality of evidence was low. SSZ may also affect male fertility, with oligospermia, reduced sperm motility and increased proportions of abnormal sperm previously reported [1]. No further studies of paternal SSZ exposure were identified in our search.

Leflunomide

Previously, we identified a cohort study [52] and case report [413] describing outcomes from ($n = 2$) pregnancies after paternal exposure to LEF within three months of conception, and subsequent pregnancy exposure (with intercourse without a condom) in at least one case with no reported washout. No adverse foetal outcomes were observed. An additional study was identified examining foetal outcomes with paternal leflunomide (and other DMARD) use compared with abatacept; however, outcomes for individual drugs were not reported [375].

Downloaded from https://academic.oup.com/rheumatology/advance-article/doi/10.1093/rheumatology/keac551/6783012 by guest on 03 February 2023

Azathioprine

In addition to the previous 602 paternal exposures [52, 404–409, 414, 415], we identified three studies of $n = 2680$ pregnancies after paternal exposure to AZA [185, 187, 216]. Overall, no increased risk of adverse foetal outcomes was observed.

Ciclosporin

In addition to previous studies [406, 408, 410, 416] on outcomes from pregnancies ($n \geq 254$) after paternal exposure to CsA, we found a Danish population-based cohort study of birth outcomes in 247 children fathered by men treated with CsA before conception [185]. Overall, these studies did not identify an increased risk of adverse foetal outcomes with paternal exposure to CsA.

Tacrolimus

No additional paternal studies were found to complement previous findings reporting outcomes from pregnancies ($n \geq 120$) after paternal exposure to tacrolimus, which did not identify an increased risk of adverse foetal outcomes [406, 416, 417].

Cyclophosphamide

No new studies of paternal exposure to CYC were identified. In addition to a potential long-term impact on spermatogenesis (and hence fertility) in men [418], there is evidence of an adverse impact on germ cell development and male-mediated teratogenicity from animal studies [419–422], although this has not been proven in humans [423–425].

Mycophenolate mofetil

In addition to the three previous studies [406, 416, 426] of paternal exposures to MMF ($n \geq 72$), we found three additional studies of pregnancies ($n = 220$) after paternal exposure [185, 246, 247]. Overall, the quality of these studies was low, but they did not identify an increased risk of adverse foetal outcomes.

Intravenous immunoglobulin

There is no evidence relating to paternal exposure but based on maternal compatibility it is unlikely to be harmful.

Anti-TNFα drugs

Previously, we found five cohort studies [52, 263, 405, 412, 427], two case series [404, 410], two case reports [428, 429] and a case-control study [409] that reported on outcomes from pregnancies ($n = 131$) after paternal exposure to INF, ETA and ADA. Overall, the quality of these studies was deemed to be low, but they did not identify an increased risk of adverse foetal outcomes. We identified an additional eight cohort studies reporting outcomes from 620 pregnancies after paternal exposure to TNFi [293, 298, 306, 430–434], with no significant findings to suggest adverse foetal outcomes were more likely after TNFi exposure.

Rituximab

We did not identify any further paternal exposures to the 11 found previously [343], which did not identify any problems in relation to paternal exposure to RTX.

IL-6 Inhibitors

Two studies of $n = 15$ paternal exposures to TCZ did not find any drug-related effects [357, 359].

IL-1 Inhibitors

One study of $n = 5$ paternal exposures to anakinra did not find any drug-related effects [369]. Youngstein *et al.* reported on five healthy pregnancies to three fathers on long-term canakinumab treatment [369].

Abatacept

In addition to the previous case of one healthy pregnancy following paternal ABA exposure [374], a study of clinical trial and post-marketing data submitted to the manufacturer (up to 2014) reported 10 paternal ABA exposures, resulting in nine healthy live births with one elective termination [375].

IL-17 inhibitors

Two studies of paternal exposure to secukinumab ($n = 54$) and ixekizumab ($n = 34$) did not report any adverse drug-related effects [387, 389].

JAK-inhibitors

There were 87 paternal exposures to TOF in a study included in our search [397]. Further details provided by Pfizer reported paternal exposures to TOF in the PsA clinical trials ($n = 3$) and post-marketing reports ($n = 3$), described above. During the RA and psoriasis clinical trials programmes, 66 men were exposed to TOF with 45 known outcomes, including 37 normal healthy newborns, two premature deliveries (with one subsequent neonatal death) and six spontaneous miscarriages [400]. In the UC clinical trial programmes, there were 19 paternal exposures with 17 known outcomes (15 healthy newborns including one healthy preterm delivery at 34 weeks, and two spontaneous miscarriages) [398]. Data provided by Eli Lilly included eight paternal exposures to BAR in the clinical trials programmes, and outcomes included six full-term healthy newborns and two spontaneous miscarriages [402].

No data were found relating to paternal exposure to BEL, IL-12/23i or anifrolumab.

Recommendations for paternal exposure to immunomodulatory drugs

i) Due to the adverse effect of CYC on male fertility, semen cryopreservation is recommended for men prior to paternal exposure (GRADE 1C, SOA 99.5%).
ii) Men who take SSZ may have reduced fertility. There is little evidence to suggest that SSZ should be stopped preconception, unless conception is delayed by more than 12 months when stopping SSZ should be considered along with other causes of infertility (GRADE 1C, SOA 99.0%).
iii) Paternal exposure to the following anti-rheumatic medication is compatible with pregnancy: prednisolone, low-dose (≤25 mg/week) MTX, AZA (GRADE 1B); TNFi, cyclosporin (GRADE 1C); HCQ, LEF, tacrolimus, MMF, IVIG, RTX, IL-6i, IL-1i, ABA, BEL, IL-17i, UST and JAKi (GRADE 2C, SOA 99.3%).

Applicability and utility

Implementation

Awareness of these guidelines will aid clinical practitioners and patients in decision making and will be raised through presentation at local, regional and national meetings. No barriers to implementation of these guidelines are anticipated.

Key standards of care

Ideally, patients with rheumatic disease should receive tailored pre-pregnancy counselling and then be reviewed during pregnancy and the four-month post-partum period by clinical practitioners with expertise in the management of rheumatic disease in pregnancy, in addition to their routine obstetric care. They should have access to written information on relevant medications in pregnancy and breastfeeding that is accurate and allows them to make informed decisions regarding compatibility of certain drugs in pregnancy.

Future research agenda

The limitation of current evidence highlights the need for a national pregnancy registry for patients with rheumatic disease, as currently exists for women with epilepsy. All women with rheumatic disease who become pregnant would be eligible to register, whether or not they are on anti-rheumatic treatment. The prospective pregnancy outcome data would then be published to display information on outcomes such as miscarriage and congenital anomalies in patients treated with anti-rheumatic therapy. These data would also be used to answer specific questions such as the most suitable time to stop MTX pre-conception. Data relating to the impact of paternal exposure to these drugs (both fertility and male-mediated teratogenicity), as well as breastmilk exposure, are particularly limited, and further research in these areas is urgently required. Other research questions include: should bDMARDs with known placental transfer be stopped or switched before/during pregnancy; are tsDMARDs compatible with pregnancy; is it safe to give certain live vaccines to infants $\leq$6 months after *in-utero* exposure to bDMARDs with known placental transfer in the third trimester of pregnancy?

Mechanism for audit of the guideline

An audit pro forma to assess compliance with these guidelines is shown in the audit tool in Supplementary Data S5, available at *Rheumatology* online.

Supplementary data

Supplementary data are available at *Rheumatology* online.

Data availability statement

All relevant data produced during the guideline development process are presented in the guideline or in the accompanying supplementary material.

Funding

No specific funding was received from any bodies in the public, commercial or not-for-profit sectors to carry out the work described in this manuscript.

Disclosure statement: All authors have made declarations of interest in line with BSR policy (see Supplementary Material, available at *Rheumatology* online). L.M. has received honoraria from UCB and educational funding support from Abbvie and Pfizer. C.G. has received honoraria from Abbvie, Alumis, Amgen, Astra-Zeneca, MGP, Sanofi and UCB. C.-S.Y. has received honoraria from Amgen. K.Sc. has received educational support from UCB and honoraria from UCB and Thermo-Fisherworks and a Novo Nordic Foundation research grant. L.W. has received honorarium from Novartis. M.R. has received educational funding support from Lilly, Pfizer, Janssen and UCB and honoraria from Lilly, Menarini and Biogen. S.T. has received honoraria from UCB. I.G. has received honoraria and unrestricted research grants from UCB. K.H. has received honoraria and educational support from UCB. M.G. has received honoraria from UCB, Lily and Abbvie. M.K. is an employee of GSK and gave independent expert advice to the Working Group. The remaining authors have declared no conflicts of interest.

Acknowledgements

A full list of Standards, Audit and Guidelines Working Group members can be found in Supplementary Data S6, available at *Rheumatology* online. All contributing members are named in the authorship list.
